THE MAINTENANCE OF PATIENTS WITH TROPICAL SPRUE BY MEANS OF MASSIVE DOSES OF SYNTHETIC 5 METHYL URACIL (THYMINE). G G Lopez, F Milanes, R L Toca, T Aramburo and T D Spies. From the Department of Nutrition and Metabolism, Northwestern University and the Department of General Pathology, University of Havana, Havana, Cuba. *Am J M Sc* 216: 270-274, 1948.

Three patients with tropical sprue have been maintained in complete hematologic remission for at least a year on oral thymine therapy. There was no evidence of subacute combined degeneration at any time. The patients, according to the authors, were asymptomatic with completely normal stools after the first six weeks of therapy. Two of the patients were maintained on 5 grams of thymine per day. The third patient received 15 grams of thymine for 30 days and none thereafter.

G.E.C.

EFFECT OF PTERIDINES AND BLOOD SERA ON HUMAN BONE MARROW CELLS IN VITRO. E R Norris and J J Majnarić. From the Department of Biochemistry, University of Washington, Seattle, Washington. *Am J Physiol* 153: 496-498, 1948.

Pteridines and blood sera have been shown to cause a cellular proliferation in vitro of bone marrow suspensions of the rat, rabbit, cat, sheep, and beef. This work was done to determine the effects on the bone marrow of the human. Rib marrow was obtained by surgery and a suspension was prepared in Tyrode's solution without glucose. Ten mg. of hydrolysate and 0.5 mg. of tryptophane were added per ml. of cell suspension. Proliferation was determined by means of cell counts. Xanthopterin increased the rate of cell proliferation while antixanthopterin inhibited this proliferation.

R.C.C.

A METHOD FOR STUDYING THE EFFECT OF VARIOUS SUBSTANCES UPON RED CELL MATURATION IN VIVO. E E Hays. From the University of Vermont College of Medicine, Burlington, Vermont. *Am J M Sc* 216: 528-533, 1948.

An in vitro cell survival technic using rat bone marrow and based on the reticulocyte increase after three hours incubation at 38°C in various dilutions of glucose free Tyrode's solution is described. Data are given which indicate that maturation of the red cells is stimulated by anti-pernicious anemia liver extracts and not by various other substances including an inactive liver extract. Pteroylglutamic acid and pteroylheptaglutamic acid were inactive when so assayed. Normal human serum and rat serum exhibited the presence of the maturation factor required by this technic.

G.E.C.

INFLUENCE OF THE DOSAGE OF XANTHOPTERIN UPON THE RESPONSE IN HEMOPOIESIS. E R Norris and J J Majnarić. From the Department of Biochemistry, University of Washington, Seattle, Washington. *Am J Physiol* 153: 133-137, 1948.

Young rats were made anemic by feeding a purified diet containing one per cent sulfathiazole. A single injection of less than 5 mg. of xanthopterin per kilogram of body weight produced hemoipoiesis. At

results were obtained with 10 mg. Doses of 20 mg. or more aggravated the anemia. Normal rats were also studied. Similar results were obtained.

RCC

**INTRAVENOUS IRON THERAPY** *A. J. Agner, N. S. E. Andersson and N. G. Nordinson* Mediz. Klinik und Chem. Laboratorium des Serafimerlasarettet & II. Med. Poliklinik, Stockholm. *Acta haematologica* 1: 193-211, 1948.

Twenty cases of iron-deficiency anemias were treated with intravenous injections of a special chemical compound of ferric iron. In 17 cases an increase of the hemoglobin, the number of the erythrocytes, the reticulocytes and the serum iron was observed as an effect of this treatment. In 19 cases there was a special favorable effect on the symptoms and on the epithelial signs.

Side effects in connection with the injections were not noticed. Paravenous injection of the iron solution must be avoided.

CM

**INTRAVENOUS IRON IN THE TREATMENT OF ANAEMIA OF PREGNANCY** *A. D. T. Gowan and J. M. Scott* From the Glasgow Royal Maternity and Women's Hospital, Scotland. *Lancet* 1: 14-16, 1949.

Ferrivenin (saccharated oxide of iron) was used to treat 25 patients with anemia of pregnancy. All the patients responded to treatment and the response compared favorably to that obtained in 62 similar patients given iron by mouth. Two patients apparently refractory to iron by mouth responded to the intravenous iron. One patient had a severe reaction and about 10 per cent showed a slight general reaction at the first or second injection but not subsequently.

The pregnant anemic women appeared to need more iron than nonpregnant women to restore the hemoglobin values to normal, i.e. almost 40 mg. of iron for every 1 per cent increase in hemoglobin, perhaps due to the demands of the fetus.

SC

**INTRAVENOUS TREATMENT OF ANAEMIA WITH AN IRON-SUCROSE PREPARATION** *H. G. B. Slack and J. F. Wilkinson* From the Department of Haematology, Manchester Royal Infirmary, England. *Lancet* 1: 11-14, 1949.

After trial of many different iron preparations it was found that Seitz filtered ferric oxysaccharate B.P. (1 per cent iron) could be given intravenously in large doses without producing toxic symptoms. Sixty patients with iron deficiency anemia were treated: about a third of them with a home-made preparation and the remainder with Ferrivenin (Bengers Ltd.). The total blood iron deficit was calculated in each patient and 50 per cent added for depleted body stores. The usual scheme of dosage was 25 mg., increasing daily up to 200 mg. on the fourth and subsequent days until the total calculated dose had been given. Only one patient developed a mild reaction to 200 mg. but larger doses gave more frequent reactions. Fifty-seven of the 60 patients, including some refractory to oral iron, showed a striking therapeutic response. Utilization of iron appeared to be nearly 100 per cent, urinary loss being negligible. Two patients with chronic infection showed a response but required more than the calculated amount to maintain improvement.

This experience with intravenous saccharated oxide of iron confirms a real therapeutic advance. The suggestion that the anemia of infection may respond to this form of iron is especially interesting and clearly needs confirmation.

An amendment to the method of preparation and further details are given in a letter from these authors in *Lancet* 1: 163, 1949. They also give a warning against the irritant action of the iron preparation if allowed to leak around the vein.

SC

## LEUKOCYTES, LEUKEMIA, LYMPHOMA

**THE DIFFERENTIATION OF THE NEUTROPHIL LEUKOCYTES** *K. Reber* Mediz. Universitätsklinik, Zürich. *Acta haematologica* 1: 98-108, 1948.

The conception of the neutrophil stab-cell is critically analyzed and it is shown that by strictly using Schilling's definition only the lack of segmentation of this cell group is taken into consideration. While

the name of stab-cells should express at the same time a lack of lobulation of the nucleus. It is pointed out, that the tendency to lobulation of the nucleus and the degree of segmentation of the nucleus have from the genetic point of view a different origin. The lobulation of the nucleus respectively the definitive number of the segments is dependent on the form of the maturing myelocytes but the extent of segmentation is regulated by the speed of maturation and emigration. Those two functions are controlled by the vegetative nervous system the formation of the cells is under parasympathetic the maturation and emigration under sympathetic influence. It is suggested that from now on one should distinguish only between segmented and unsegmented neutrophils and to record separately the number of the segments either developed or still in development.

C.M.

THE INFLUENCE OF PHYSICAL AND CHEMICAL AGENTS ON THE MOVEMENT OF LEUKOCYTES *P. Scharrer*  
Anatomisches Institut der Universität Zürich *Acta haematologica* 1 178-192, 1948

A method is described for the measurement of movements of isolated cells. The results of the measurement concern the influence of hypotony and hypertony, colchicine, acetone, alcohol, chloralhydrate, stilbestrol and cibazol and they are compared with the influence on the development of mitoses in fibrocytes.

C.M.

CHANGES IN THE BLOOD LEUCOCYTE LEVEL OF ADRENALECTOMIZED AND NORMAL RATS FOLLOWING ADMINISTRATION OF TYPHOID VACCINE *L. A. Lewis and I. H. Page* From the Research Division of the Cleveland Clinic Foundation, Cleveland, Ohio. *Am. J. Physiol.* 153 148-152, 1948

Previous work has indicated that toxic agents introduced into the body produce a decrease in the circulating lymphocytes through the action of the adrenal cortex. This work was done to determine whether there would be any response to typhoid vaccine in the absence of the adrenal glands. Fifty-six adult male rats of the Sprague Dawley strain were used. They were adrenalectomized and maintained on 0.9 per cent salt solutions. Intraperitoneal injections of typhoid vaccine markedly lowered the lymphocyte level two hours after the injection in the absence of the adrenal glands. In addition, the neutrophils increased in number. Normal human beings injected with typhoid vaccine showed similar results. It is concluded that the adrenal glands are not necessary for the lymphopenia which is induced by typhoid vaccine.

R.C.C.

THE NEGATIVE EFFECT OF FOLIC ACID ON IRRADIATION LEUKOPENIA IN THE CAT *W. S. Adams and J. S. Lawrence* From the University of Rochester School of Medicine and Dentistry and the Medical Department of Strong Memorial and Rochester Municipal Hospitals, Rochester, New York. *Am. J. M. Sc.* 216 656-660, 1948

The prophylactic and therapeutic administration of folic acid to cats did not alter the occurrence or the magnitude of leukopenia caused by exposure to 200 r whole body irradiation.

G.E.C.

STUDIES ON BLOOD HISTAMINE. PARTITION OF BLOOD HISTAMINE BEFORE AND AFTER CLOTTING IN HEALTH AND DISEASE STATES *W. N. Valentine and J. S. Lawrence* From the University of Rochester School of Medicine and Dentistry and the Department of Medicine of Strong Memorial and the Rochester Municipal Hospital, Rochester, New York. *Am. J. M. Sc.* 216 619-624, 1948

Data are presented on the partition of blood histamine before and after clotting and on the correlation of blood histamine levels with the blood leukocyte picture in health and disease states. The data support the view that most of the blood histamine in man is found in the myeloid leukocyte. Little or no transfer of histamine from cells to serum was observed when human blood was allowed to clot. Greatly increased values for blood histamine were found in patients with chronic myelogenous leukemia but no close correlation was obtained between the level of blood histamine and the total or differential leukocyte count. The studies did not permit any conclusions as to which members of the granulocyte series are richest in histamine content.

G.E.C.

LYMPHOCYTES AND INTRAVASCULAR HAEMOLYSIS *R. H. Trisick* From the South London Blood Supply Depot Sutton Surrey *Lancet* 1 225 1949

A patient with acquired hemolytic anemia accompanying Hodgkins disease showed a positive Coombs test. This was taken to indicate the intravascular hemolytic action of an immune gamma globulin. In stained films of the patient's blood many of the lymphocytes showed cytoplasmic buds especially at the time of maximum hemolysis and it is suggested that such buds becoming detached might be the source of the immune gamma globulin.

S.C.

ON SERUM COPPER IN ANGINA SIMPLEX AND IN INFECTIOUS MONONUCLEOSIS *S. March-Petersen* From the Biochemical Institute Aarhus University, from the Medical-epidemic Department, Aarhus Marselisborg Hospital and from the Medical Department of Aarhus County Hospital, Denmark *Acta med Scandinav* 131 588, 1948

Serum copper was determined with sodium diethyl-carbamate in 22 cases with angina and 20 patients with infectious mononucleosis. In both conditions the values were increased as might be supposed in a febrile condition. The values in infectious mononucleosis were much higher. The meaning of this difference is discussed but no explanations could be found.

J.W.

ARE THE BASOPHILIC LEUKOCYTES HEPARINOCYTES? *Guido Tøttersen* From the Second Medical Clinic, Helsingfors *Acta med Scandinav* 131 176, 1948

The author discusses the problem why cases of chronic myeloid leukemia with increase in the basophilic leukocytes do not show greater tendency toward bleeding than patients with the same disease but with low counts of basophilic cells. If the basophilic cells of the blood were really producing heparin this is hard to explain. The difference between tissue basophilic cells and blood basophilic cells is pointed out.

J.W.

ARTERIALGIC LEUKEMIA IN CHILDREN *J. Bichel* From the Clinical Department and the Research Laboratories of the Radium Centre of Jutland, University of Aarhus *Acta haematol* 1 153-164 1948

The author stresses the frequent occurrence of osteo-articular symptoms in the early stages of leukemia in children. Many such cases have for a time been mistaken for acute rheumatic fever. In early infancy rheumatic symptoms will always indicate a careful examination of the blood (often including the bone marrow as the blood picture may be almost normal until terminally). The relation between the articular symptoms and the radiographically demonstrable bone lesions is discussed. The value of the roentgenologic examination of the skeleton in obscure cases is emphasized. The literature is surveyed, and three characteristic case reports are presented.

C.M.

MONOCYTIC LEUKEMIA (CASE REPORT OF A NAEGLI TYPE) *H. Diekmann and H. van Ijzeren* From the Medical University Clinic, Utrecht (Holland) *Acta haematologica* 1 55-59 1948

Monocytic leukemia is briefly discussed and a case of the Naegli type is reported. The monocytoid elements which were originally found changed their character and more and more resembled myeloblasts, finally only paramyeloblasts and myeloblasts were observed. Sternal puncture made an early diagnosis possible.

C.M.

LYMPHOSARCOMA TERMINATING IN LYMPHATIC LEUKEMIA (LYMPHOSARCOMA CELL LEUKEMIA) *L. Hauswirth, G. Resnew and W. Lansman* From the Departments of Medicine and of Pathology, Beth David Hospital, New York New York *Acta haematologica* 1 45-54 1948

A case is presented in which the patient when first seen had the histologic findings of lymphosarcoma with normal blood and bone marrow a year later an acute lymphatic leukemia developed with rapidly fatal course. The transition of the lymphosarcomatous to the leukemic phase could be followed by serial blood, sternal and iliac bone marrow and tissue studies and confirmed at autopsy.

The cells of the blood marrow and the lymphnodes have the characteristic features of lymphosarcoma cells. Consequently the disease can be classified as lymphosarcoma cell leukemia.

The possibility is discussed whether ro-nitrogen and nitrogen mustard therapy induced or enhanced the appearance of the leukemic phase.

C M

THE ELECTROPHORETIC ANALYSIS OF SERUM PROTEINS OF THE BLOOD DYSCRASIAS. R. A. Brown, J. T. Read, B. A. Wiseman and W. G. France. From the Departments of Medicine and Chemistry, The Ohio State University, and the Starling Loving University Hospital, Columbus, Ohio. *J. Lab. & Clin. Med.* 33, 1523-1533, 1948.

The electrophoretic patterns of various blood dyscrasias are presented. The leukemic states are associated with a diminution in the approximate absolute amount of albumin and a rise in the absolute amount of globulin. The albumin globulin ratios fall below the limits of normal in most instances. The alpha 1 and alpha 2 globulin are increased in most instances and the increase is noted with both normal and diminished total albumin values. Gamma globulin values, both absolute and relative, were elevated in monocytic leukemia, reticulum cell sarcoma, and infectious mononucleosis. Chronic lymphatic leukemia demonstrated low relative and absolute gamma globulin values. A markedly lowered albumin globulin ratio appears related to the degree of infiltration of the bone marrow by leukemic cells as well as when the excretory and metabolic functions of the liver demonstrate impairment. No alteration in the serum protein architecture was noted following Stilbamidine therapy.

G.E.C.

THE INTERRELATIONSHIP OF HODGKIN'S DISEASE AND OTHER LYMPHATIC TUMORS. R. P. Carter and W. G. Bernhard. From the Army Institute of Pathology, Washington, D. C., and the Laboratories of the Presbyterian Hospital in Philadelphia, Pennsylvania. *Am. J. M. Sc.* 216, 625-642, 1948.

During the last war the authors were assigned to the Army Institute of Pathology to render a report on all lymphatic and hemopoietic tissue submitted. The present paper is a summary of a pathologic study involving 1300 lymphatic tumors including 700 cases of Hodgkin's material and 600 cases of lymphomas (follicular lymphoblastoma, lymphosarcoma, reticulum sarcoma, lymphatic leukemia, monocytic leukemia) apart from Hodgkin's disease. The authors conclude that a rigid subclassification of lymphatic tumors is artificial and confusing. In their material there was a striking fluidity in histologic pattern with transitions and combinations that could best be interpreted as indicating a single neoplastic entity having a number of variants. As they state, this is not surprising when one appreciates that all cellular components of lymphatic tissue are derived from the same mesenchymal stem cells.

A virtually complete alteration in the histologic pattern of the tumor in the Hodgkin's group was noted in 39 per cent of the 138 autopsied cases in which biopsies were available and in 31 per cent of the serial biopsy group. Pure tumor types were present in only 19 per cent of the autopsy group and in 23 per cent of the serial biopsy group. The variety of histologic appearances observed in different foci in the same individual, and even in several areas in the same node, was still more spectacular. Three hundred eighty-four of 700 cases presented these combined lesions. Lymphomas not grouped with Hodgkin's disease also exhibited an alteration of their histologic structure in much the same fashion.

G.E.C.

## BONE MARROW AND RETICULOENDOTHELIAL SYSTEM

THE OCCURRENCE OF EPITHELIOID CELL GRANULOMAS IN HUMAN BONE MARROW. H. Gormsen. From the University Institute of Legal Medicine, Copenhagen. *Acta med. Scandinav. Suppl.* 213, 154-164, 1948. *Studia in Honorem Einar Meulengracht*.

Histologic sections of sternal aspirates showed typical granulomas in 10 of 39 patients with Boeck's sarcoid, in 5 of 5 patients with milary tuberculosis, and in 15 of 22 patients with brucellosis.

J W

A HEMATOLOGICAL AND HISTOLOGICAL STUDY OF THE BONE MARROW AND PERIPHERAL BLOOD OF THE ADULT DOG. P. E. Rekers and M. Coulter. From the Department of Radiation Biology, The University of Rochester School of Medicine and Dentistry, Rochester, New York. *Am. J. M. Sc.* 216, 643-655, 1948.

This is probably the most extensive study of the peripheral blood and bone marrow of the normal dog which has as yet been published and has promise of serving as the standard reference of this subject for some time to come. It is regrettable, however, that volume of packed red cell measurements were not done and values for the red cell indices calculated. Analysis of the peripheral blood of 91 normal dogs is presented including differential white cell counts. Bone marrow differential counts from the ribs, femora, tibiae and humeri are presented, compared and analyzed statistically. Bone marrow total nucleated cell counts are given for one or more sites from 4 different bones. Rib bone marrow has been studied at 2, 3, 4, 5 and 8 hours after death and no significant alterations in degree of cellularity and cellular detail was found. Histologic studies are also included.

G E C

EXPERIMENTAL OBSERVATIONS ON THE STRUCTURE OF THE BONE MARROW. A. Nèzet. From the Université de Liège. Institut de Clinique et de Policlinique Médicales. Quart. J. Exper. Physiol. 34: 43-46, 1947.

This work was undertaken to determine whether ripe erythrocytes were stored in the bone marrow. Dog A was injected with 30 mg. of phenylhydrazine per Kg. of body weight which produces Heinz's granules in a large percentage of the dog's erythrocytes. After allowing time for all phenylhydrazine to be eliminated, the circulation of dog A is crossed with another dog, dog B. In this way the labelled erythrocytes were introduced into dog B. This crossed circulation was maintained from thirty minutes to one hour. By means of this technique the author found that no ripe erythrocytes were stored in the bone marrow and concluded that all red cells achieve their ripening in the circulating blood.

R C C

AN APPLICATION OF BONE MARROW CULTURES TO TOXICOLOGY AND THERAPEUTICS. K. Harrison and F. W. Randall. From the Chemical Defence Experimental Station, Porton, near Salisbury. Quart. J. Exper. Physiol. 34: 141-148, 1948.

The author points out that the intact animal is not always the best thing to use in the study of toxicology. He describes a method of using tissue cultures of bone marrow for the study of the toxic actions of drugs.

R C C

ARE NON NUCLEATED ERYTHROCYTES FORMED BY BUDDING OFF OF CYTOPLASM FROM NORMOBLASTS? Lissa Bæstrom. From Central Clinical Laboratory of Södersjukhuset, Stockholm. Acta med. Scandinav. 131: 303, 1948.

The still unsolved problem of the denucleation of red blood cells or the separation of cytoplasm from the erythroblasts in the marrow is discussed. A large number of morphologic observations that seem to indicate that the hypothesis of protoplasmic budding may be correct are presented. Also the bone marrow cultures by Plum are regarded as proof that this explanation should be accepted. The presence of unripe reticulocytes with a structure possibly indicating a scar from the stalk after the budding is also interpreted in the same way. The paper should be read in the original by all those who are interested in the problem of erythrocyte formation.

J W

THE HISTOGENESIS AND DIAGNOSIS OF THE OSSEOUS TYPE OF GAUCHER'S DISEASE. M. Block and L. O. Jacobson. From the department of Medicine, University of Chicago, Chicago, Illinois. Acta haematologica 1: 165-177, 1948.

The diagnosis of Gaucher's disease depends upon the demonstration of the glucose containing cerebroside or of the characteristic Gaucher cell. The disease can be diagnosed before the appearance of hepatomegaly or splenomegaly.

The study of properly prepared sections of the bone marrow is a more certain method of diagnosis than the study of sternal puncture smears. Gaucher's disease is not a disease of the reticulo-endothelial system. The reticular cells, osteoblasts, osteoclasts and fibroblast like spindle cells of bone and marrow are the source of the Gaucher cell. The Gaucher cell is morphologically distinct from the cells found in the other fat storage diseases. Evidence is offered that red cells in the marrow in Gaucher's disease are present outside of what is ordinarily conceived to be blood vessels.

C M

RETICULO-ENDOTELIOSIS PALUDICA. (MALARIAL RETICULO-ENDOTHELIOSES) *C Martínez Mejía* Medicina (Revista Mexicana) 28 417, 454 459 481 1948

The paper begins with an anatomic description of the reticulo-endothelial system (issue 565), followed by a discussion of its physiology in relation with malarial fever (issue 566) and of its pathology in various infectious diseases (issue 567). Most of the photomicrographs have been taken from the collection of Dr. Soberon y Panra. The endo- and exoerythrocytic cycle of the plasmodium is stressed; the latter taking place in the reticuloendothelial cells where they remain in a latent state. This localization of the plasmodium, which appears to be most important, explains the therapeutic failures of most antimalarial drugs. She believes that the anemia of malarial fever is not only due to the destruction of the erythrocytes in the peripheral blood, but also to a block and degeneration of the hematopoietic organs. For the study of malarial reticuloendotheliosis she recommends the methods of Henry and Soberon.

R.M.S.

## HYPERSPLENISM

SPLENECTOMY IN THE RETICULOSSES. *L. J. Wills* From the Radcliffe Infirmary, Oxford, England. Acta med Scandinav Suppl 213, 352-364 1948. Studia in Honorem Einar Meulengracht.

The indications for splenectomy in 6 patients with reticuloses are discussed. In 2 patients the spleen was removed in order to alleviate pressure symptoms, in 2 for leukopenia, in 1 for thrombocytopenia. The effect was favorable in 5. In one patient a diagnostic splenectomy had no favorable effect.

J.W.

MYELOSCLEROSIS. A CASE WITH NON-MYELOID SPLENOMEAGLY AND AN ATTEMPT AT FINDING OUT THE PATHOGENESIS BY MEANS OF COMPARISON WITH RESULTS OF ANIMAL EXPERIMENTS. *H. C. Engell* From the Medical Department of the Frederiksberg County Hospital, Denmark. Acta med Scandinav 129 371 1947.

Splenomegaly and myelosclerosis were present in this patient and the author regards the changes in the spleen as nonleukemic. Splenectomy was performed at an early stage on the assumption that there was present a splenogenic inhibition of the marrow. The correctness of this explanation may be questioned but there was definitely an increase in leukocytes after operation. Later the patient died with anemia and thrombocytopenia but no leukopenia. The bone marrow showed increased fibrosis and the diagnosis was myelosclerosis. No extramedullary hemopoiesis was found.

J.W.

SPLENIC NEUTRO-THROMBOPENIA. *J. Bisbet* From the Roentgen Clinic of the Aarhus Municipal Hospital and the Radium Center for Jutland, Aarhus, Denmark. Acta med Scandinav Suppl 213 74-81 1948. Studia in Honorem Einar Meulengracht.

The history of a man 25 years old, who had suffered since childhood from recurrent stomatitis, angina and profuse nosebleeds is given. There was no anemia but the leukocytes decreased from 3,000 in January 1943 to 760 in February 1945. Platelets low. No signs of myeloblastosis in the bone marrow. Splenectomy gave prompt objective and subjective cure. Observation time two years. The patient's brother had typical symptoms of acute leukemia clinically. The possibility of a connection between the two diseases is pointed out.

J.W.

HYPERSPLENISM. SOME PRELIMINARY OBSERVATIONS. *W. Dameshek, and S. Estrin* From the Blood Laboratory of the J. H. Pratt Diagnostic Hospital, Boston, Massachusetts and the Department of Medicine, Tufts College Medical School, Boston, Massachusetts. Acta med Scandinav Suppl 213 106-119, 1948. Studia in Honorem Einar Meulengracht.

The paper gives an essence of Dameshek's ideas about hypersplenism with some illustrative case histories showing the importance of splenectomy.

J.W.

## BLOOD VOLUME

**DETERMINATION OF CIRCULATING RED BLOOD CELL VOLUME WITH RADIOACTIVE PHOSPHORUS** *R T Nisset, B Porter, W V Trautman, Jr, R M Bell, W Parson, C Lyons, and H S Mayerison* From the Laboratory of Biophysics Departments of Medicine, Surgery, and Physiology Tulane University School of Medicine and the Alton Ochsner Medical Foundation, New Orleans Louisiana *Am J Physiol* 155 226-231, 1948

The authors have presented a method for determining total circulating red blood cell volume by an isotope diluting technic using radioactive phosphorus. The authors point out that the subject to be studied is utilized for the labeling, that the counting is easy that determinations can be repeated, and that the rapid uptake and slow release of radioactive phosphorus by exposed red cells facilitates wide experimental application. Details of the method are too complex to put in abstract form.

R.C.C.

**COMPARISON OF RESULTS OF MEASUREMENTS OF RED BLOOD CELL VOLUME BY DIRECT AND INDIRECT TECHNIQUES** *H S Mayerison, C Lyons, W Parson, R T Nisset and W V Trautman, Jr* From the Departments of Physiology, Surgery, and Medicine and the Laboratory of Biophysics Tulane University School of Medicine and the Alton Ochsner Medical Foundation New Orleans, Louisiana *Am J Physiol* 155 232-238, 1948

The object of this experiment was to compare the results obtained with the dye method for determining red cell volume with the method utilizing radioactive phosphorus (*Am J Physiol* 155 226-231 1948). Concomitant measurements of red cell mass and plasma volume were made with the P 32 technic and the T 1824 method on 10 normal and 35 hospitalized patients. A standard correction factor of 0.915 was used to correct the hematocrit values for trapped plasma. Total blood volumes were calculated from the red cell volume and hematocrit and from the plasma volume and hematocrit. These values were compared with the total blood volume as calculated from the sum of the actually determined red cell and plasma volumes and showed satisfactory agreement. The data show that the plasma-dye hematocrit method is valid provided the corrected hematocrit value is used.

R.C.C.

**MEASUREMENT OF CIRCULATING RED-CELL VOLUME WITH METHEMOGLOBIN TAGGED CELLS** *J C Moore, O W Shadle and H C Lawson* From the Department of Physiology, University of Louisville School of Medicine, Louisville Kentucky *Am J Physiol* 155 322-329 1948

Circulating red cell volumes were determined on splenectomized barbiturized dogs by means of the conventional dye method and also by injecting a suspension of red cells containing large amounts of methemoglobin. The latter method always gave values that were lower than by the dye method even after corrections were made for the injected material.

R.C.C.

**DETERMINATION OF BLOOD VOLUME IN DOG BY MEANS OF VISUALLY LABELLED ERYTHROCYTES** *A Niget* From the Institut de Clinique et de Polyclinique Médicales Université de Liège *Quart J Exper Physiol* 34 123-128 1948

This study was undertaken to determine blood volume by means of labelling erythrocytes with Heinz granules by injections of phenylhydrazine. A known volume of labelled blood was injected intravenously into a dog and a blood sample removed five to forty minutes after the injection. By using a formula which is given the blood volume can be determined by counting the erythrocytes containing granules. The average circulating blood volume was found to be 66 cc per Kg of body weight.

R.C.C.

**EFFECT OF THE ADMINISTRATION OF ADRENALIN ON THE CIRCULATING RED CELL VOLUME** *W Parson, H S Mayerison, C Lyons, B Porter and W V Trautman, Jr* From the Departments of Physiology, Surgery and Medicine Tulane University School of Medicine and the Alton Ochsner Medical Foundation New Orleans Louisiana *Am J Physiol* 155 239-241 1948

This experiment was conducted to test the theory that there is a reserve of red blood cells in the spleen which can be utilized by the body in cases of emergency. Three normal adults, one patient with rheumatoid arthritis and one patient with hemolytic anemia were studied. After preliminary studies had determined the normal plasma and red cell volumes (by the dye and radioactive phosphorus methods) normal peripheral and body hematocrits and protein level each person was injected with 1 mg. of adrenalin. One man who expected adrenalin was given saline. This amount of adrenalin did not result in any significant changes in the plasma or red cell volumes. The authors conclude that if sympathetic stimulation or adrenaline influence these functions the effect must be very slight and of no real significance as an emergency response.

R.C.C.

## BLOOD COAGULATION AND HEMORRAGIC DISEASES

THE EFFECT OF NITROGEN MUSTARD AND X IRRADIATION ON BLOOD COAGULATION. L. O. Jacobson, E. K. Marks, E. Gasson, J. G. Allen and M. H. Block. From the Biology Division of the Argonne National Laboratory and the Department of Medicine, University of Chicago. Chicago, Illinois. J. Lab. & Clin. Med. 33: 1566-1578, 1948.

The administration of 3 or 4 mg. of nitrogen mustard per kilogram of body weight to rabbits produced a prolongation of the clotting time. The same syndrome was produced in human beings after therapeutic doses of this drug. The amount of protamine necessary to produce clotting in the heparin tolerance test was increased and the prolonged clotting time and decreased heparin tolerance were reversible with antihypertensive substances. The values for calcium, prothrombin and fibrinogen were normal. The platelets were reduced but prolongation of the clotting time took place prior to a significant reduction in platelets. The authors conclude that the anticoagulant present in the blood is probably heparin or a heparin-like substance.

G.E.C.

QUANTITATIVE STUDIES ON THE COMPARATIVE ACTIVITY OF CALCIUM AND CHEMICALLY RELATED IONS ON THE COAGULATION OF BLOOD. M. Stefanini and A. J. Quick. From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wisconsin. Am. J. Physiol. 152: 389-396, 1948.

Studies were made on the blood of man, dogs and rabbits. All calcium was removed from blood by treatment with Amberlite IR 100. The blood was then treated with varying concentrations of calcium, barium, strontium and magnesium to test the effects on coagulation. The optimal amount of calcium for coagulation was found to be the same as is found in blood normally. All the above mentioned elements have an inhibitory action on coagulation when increased above the optimal level.

PLATELET EXTRACTS, FIBRIN FORMATION AND INTERACTION OF PURIFIED PROTHROMBIN AND THROMBOPLASTIN. A. G. Warr, J. H. Fabry and W. H. Seegers. From the Department of Physiology, Wayne University College of Medicine, Detroit, Michigan. Am. J. Physiol. 154: 140-147, 1948.

The object of this experiment was to determine the exact role of the platelets in blood coagulation. This study was aided by the availability of purified preparations of a number of the principal factors which participate in clotting reactions. Bovine platelet extracts contain an accelerator of prothrombin activation and only a small amount of thromboplastin. This accelerator is in an active form and acts in a similar manner to serum A<sub>2</sub> globulin. It is apparently a protein. Bovine extracts also contain a factor which hastens the second stage of clotting. The authors postulate that platelets aid in the initial formation of thrombin by catalyzing the interaction of prothrombin and thromboplastin. This thrombin then activates the inert plasma A<sub>2</sub> globulin to its active counterpart, serum A<sub>2</sub> globulin, which acts as the principal accelerator of the first stage of clotting.

R.C.C.

HEREDITARY HAEMORRAGIC TELEANGIECTASIA AND ITS RELATIONS TO OTHER INBORN VASCULAR MALFORMATIONS. H. M. Cohn, London and F. E. Rosenthal, Leicester. Acta haematologica 1: 81-91, 1945.

A report of two cases of multiple hereditary telangiectases with recurrent hemorrhages (Rendu Osler) is presented and compared with other cases of external and internal types of this condition with special regard to multiple telangiectases of the nervous system and other inborn vascular malformations.

In the first case the developmental error was not restricted to the structure of the telangiectatic malformations but extended besides to a degeneration of the collagenous and elastic tissue of the skin outside the telangiectases.

The second case offered the rare combination with a venous hemangioma of the spinal cord, causing the symptoms and signs of a cauda-conus tumor. This coincidence speaks in favor of some relationship between both inborn vascular lesions indicating a common congenital disorder of the vascular system.

The genetic connections between inborn vascular lesions of the skin and the nervous system are discussed.

C.M

**THROMBOCYTHEMIA HEMORRHAGICA** *Ole Mortensen* From the Department of Medicine Kolding Sygehus Denmark *Acta med Scandinav* 129 547 1948

The occurrence of chronic bleeding (nose, stomach and post traumatic) in spite of very high platelet counts (3-6 million) is illustrated by a case history of a man of 60 who had previously suffered from polycythemia. The erythrocyte values were exactly 5 million at the time of investigation but the leukocyte count was high (max 50 000). The syndrome is regarded as a malignant hyperfunction of the bone marrow of the same type as myeloid leukemia and polycythemia.

Obviously, the connection with polycythemia is quite intimate. A similar case is published by J. E. Holst, *Acta Medica Scandinavica* 130 507, 1948.

J.W

**THREE CASES OF POLYCYTHEMIA WITH FIBRINOPENIA** *S. E. Björkman* From the Medical Clinic of Akademiska Sjukhuset, Uppsala Sweden *Acta Med Scandinav* 129 471 1948

The author describes 3 cases of polycythemia with a bleeding tendency. Two of these cases had platelet-counts around 500,000 (normal value with the technic used 300 000). They also had low fibrinogen values but other polycythemics showed normal or increased fibrinogen values in spite of bleeding. A closer analysis of this symptom seems desirable.

J.W

## NEWS AND VIEWS

---

### JOSÉ ORIA

**I**N JULY 1948, Dr José Oriá, leading hematologist of Brazil and one of the Contributing Editors to this journal from Latin America, died in São Paulo, victim of a rare neoplasm. He was 43 years old and at the height of his professional career.

In Brazil, particularly in São Paulo, we owe a great debt of gratitude to those European physicians who, in response to the plea from the government of Brazil, came to the country and helped raise the standards of medical education. However, in the field of hematology there were no preceptors and José Oriá had to start completely on his own resources. He graduated from the Faculty of Medicine of

São Paulo in 1928, which was only fifteen years after the founding of the medical school. He was introduced to the study of morphology by the late Professor Bovero, an Italian disciple of Waldeyer, who organized the anatomy department of the medical school in São Paulo. Dr. Oria profited from the teachings of the Italian Hematologic School and in the twenty years that he worked and investigated, he contributed much to the advance of hematology in Brazil. In the last five years of his life he gave great impetus to cytochemistry and cellular enzymology. He founded the basis of modern cytology in the medical school of São Paulo. While organizing his department and arranging for original research he developed the fatal malignant disease which caused his death before the culmination of his carefully laid plans.

All scientific workers, especially physicians interested in morphology and hematology, deeply regret the loss of the man who was considered a corner stone of scientific thought in São Paulo. He had a brilliant, lucid and artistic mind and was endowed with keen powers of observation. He had the qualities of a patient and curious investigator, and was always bringing out cytologic details to the untrained eye of the student. He loved teaching in the objective way, side by side with his students. His comments often gave a rich view of the background and biologic significance of a simple slide.

Any one who ever knew José Oria has felt the loss of a friend, adviser and master.

#### CONGRESS OF THE SOCIÉTÉ INTERNATIONALE EUROPÉENNE D'HEMATOLOGIE

This year's Congress of the Society (founded 1947) will take place at Montreux, Switzerland on September 15-17, 1949. The Chairman will be Prof. Chevallier (Paris), Prof. Lambin (Louvain) and Prof. Di Guglielmo (Naples).

The principal subjects to be discussed are (1) Hemolytic anemias (main report Prof. Heilmeyer) (2) Substances with inhibitory effects on mitosis and cytostatic action (main report Prof. Haddow, London, and Prof. Dustin, Brussels).

The time limit will be 10 minutes for short reports and 5 minutes for discussions. These are to be given either in French, German or English.

Members of the International Society of Hematology are cordially invited for participation at this Congress. Announcements for participation in the European Congress are to be sent as soon as convenient to the Secretary of the Society, Dr. S. Moeschlin, Medizinische Universitätsklinik, Zurich, Switzerland.

# BOOK REVIEWS

---

*Hemolysis and Related Phenomena* By ERIC PONDER New York, Grune & Stratton 1948 \$10 398  
Pages 69 Illustrations

This book will be welcomed by new readers as well as by the many who are familiar with the author's 1934 monograph *The Mammalian Red Cell and the Properties of Hemolytic Systems* of which the present volume is distinctly more than an expansion and modernization. Although as the author states, he has been taxed with talking of the red cell as a microcosm the range of his discussion from general physiology and biophysics to the problems of hemolytic anemias in man justifies his point of view particularly as he speaks from a direct and mature experience with many of the problems. The book is divided into seven chapters and contains four appendices and an up-to-date set of references as well as information derived from unpublished experimental work of colleagues. Those who, like the reviewer, are sufficiently illiterate in the language of quantity as not to read the calculus without a dictionary will have difficulty with some of the mathematical presentations, although this is mitigated considerably by the numerous graphic representations. The reason for the extensive use of footnotes is obscure, but these *obiter dicta* are richly rewarding.

The first chapter is valuable in orienting the reader to the basic questions to be discussed and their order of presentation. The next two chapters of the book are concerned with shape changes of the red cells occurring without and with volume changes, respectively. The first set of circumstances permits simplification of the consideration of methods of measurement of the dimensions of the red cell. In the next chapter the disclosure that shape changes may be accompanied by volume changes as well raises the often debated question of whether the red cell is a baglike structure containing hemoglobin and other substances in solution or whether it has an internal structure with orientation of the molecules, as the author's discussion makes clear, is manifestly the case for the envelope. The arguments for both types of structure are well set forth and the importance of recognizing that spheroidicity of the red cells may be the result of a variety of processes is made clear.

The fifth chapter discusses extensively the kinetics of hemolysis as observed in the test tube not only from a quantitative point of view but also qualitatively with respect to the prolytic changes in the red cell and their implications concerning structure. In the next chapter, inhibition and acceleration of hemolysis are discussed. Because of the evidence that immunologic mechanisms are concerned in some of the clinical forms of red cell destruction the reader may well wish that more space had been devoted to antibody-complement systems.

The final chapter should be of particular interest to readers of *Blood* because of the description of the nature of hemolytic processes involved in disease states. Interest by students of human disease in the precise mechanisms of red cell destruction is a relatively recent development; their preoccupation heretofore being with clinical classification and estimation of the magnitude of the hemolytic process through studies of pigment metabolism. If the discussion in this chapter is less definitive than that in others, it is mainly because the difficulties inherent in the conduct of observations upon human material have led observers to diverse conclusions. Moreover, hemolytic phenomena in experimental animals and in vitro have not yet been subjected to sufficiently critical analysis to establish their relationship to the processes of disease. The material presented in Dr. Ponder's book will serve to emphasize this fact to clinical investigators and will bring together in useful form information of value to those concerned with more fundamental problems relating to the red cell and to the structure of cell membranes in general.

W. B. CASTLE

*Blood Transfusions* By ELMER L. DEGOWIN, ROBERT C. HARDIN AND JOHN B. ALSEVER Philadelphia and London W. B. Saunders Company 1949 pp. 587

There can be nothing but praise for this book. It fulfills an immediate need; it is written simply; it is thorough, and the description and picturing of the methods used in blood grouping technique are unparalleled. The work is furthermore a triumph of artistic book making, not the least of which is due to a series

of 200 remarkable line drawings illustrative of the technic used. Everything connected with transfusions is presented through the combined efforts of three authors and an artist and everyone concerned must be congratulated on having put out this outstanding addition to the literature of modern therapeutic methods and blood grouping phenomena.

WILLIAM DAMESHEK

*Experimental Immunochemistry* By ELVIN A. KABAT AND MANFRED M. MAYER. Springfield Ill. C. C. Thomas, Pages 567.

This excellent book fills a real need by bringing together for the first time the many techniques of physics and chemistry which are used and useful in the field of immunology. The authors describe these procedures clearly. Those most easily available and commonly employed such as the complement fixation reactions, are covered in careful detail with wise enumeration of technical pitfalls to be avoided. The more difficult or specialized methods such as electrophoretic analysis, are dealt with less fully though no less lucidly, the intention in such cases being to familiarize the immunochemist with the principles involved and to enable him to evaluate critically the data which appear in the literature. In each instance, not only is a technic described but the theory underlying it is presented and limitations are pointed out as background for interpretation of results.

In their preface the authors describe the arrangement of the book. Parts I and II contain a detailed treatment of immunological and immunochemical methods and their application with emphasis on the evaluation of results by the quantitative methods. In Part III are described a variety of chemical and physical methods and special procedures frequently used by the immunochemist. Part IV includes details for preparing a variety of substances of importance in immunochemical work. The only regrettable omission is that dealing with the use of ion-exchange resins in the fractionation of plasma proteins so recently described as to preclude its presentation here.

If one is to carp at anything it must be the illustrations. The halftone reproductions are at times dull and somewhat smudged. Some of the line drawings have been reduced so much as to make their lettering illegible. But this slight flaw cannot detract from the value of the work as a whole.

The field of immunology has enjoyed many fruitful years in which great progress has been made. It should be realized however that agglutinin, hemolysin, complement, etc. are relatively vague and poorly defined entities which need the technic of immunochemistry for their more exact definition. It is certainly along chemical lines that future immunologic advance will be made. Thus this book must come as a most welcome tool to the immunologist and hematologic investigator.

WILLIAM CROSBY, Major, M.C., U.S.A.

### CHRONIC CONGENITAL AREGENERATIVE ANEMIA (PURE RED-CELL ANEMIA) ASSOCIATED WITH ISO-IMMUNIZATION BY THE BLOOD GROUP FACTOR A

By CARL H. SMITH, M D

MANY VIEWS have been advanced to explain the pathogenesis of aplastic and hypoplastic anemia. The causative factors include chemical and physical agents, infection, exhaustion of the bone marrow, and specific blood dyscrasias and malignant tumors with bone marrow replacement. When these factors have been eliminated a relatively rare group of idiopathic aplastic anemia remains whose etiology is unknown and for which a congenitally inferior bone marrow has been postulated. In the classification of constitutionally defective bone marrow may be included examples of the Fanconi syndrome,<sup>1</sup> a type of anemia which is frequently familial and occurs in conjunction with a number of congenital abnormalities, chiefly pigmentation of the skin and testicular hypoplasia. Estren, Suess and Dameshek<sup>2</sup> recently described as a case of Fanconi's syndrome an 11 year old American-born child in whom hypoplastic anemia was associated with pigmentation of the skin, deafness, skeletal deformities and congenital heart disease.

It is the purpose of the present paper to describe a case reported in part of a previous communication<sup>3</sup> in which the failure of the bone marrow was confined to erythropoiesis without simultaneous depression of the granulocytes or platelets or their precursors. In considering the pathogenesis of this group of blood disorders the terms aplastic, hypoplastic and chronic congenital aregenerative anemia require definition. Aplastic anemia is a chronic progressive disease, characterized by a simultaneous depression of the three principal cellular elements in the bone marrow and resulting in a peripheral blood picture of profound anemia, leukopenia, neutropenia and thrombocytopenia. During the course of the disease the bone marrow shows a progressive decrease in the total count so that the megakaryocytes eventually disappear, the myeloid elements and nucleated red cells are greatly reduced and the lymphocytes predominate in the smears. Cases with normal or hyperplastic bone marrows with the peripheral blood picture of aplastic anemia have been interpreted as a maturation arrest or bone marrow block.

Hypoplastic anemia differs from aplastic anemia in that the formation of red blood cells is impaired with lesser involvement of the granulocytes and platelets. Earlier reports such as those of Josephs<sup>4</sup> and of Diamond and Blackfan<sup>5</sup> emphasized

From the New York Hospital and the Department of Pediatrics, Cornell University Medical College, New York, N. Y. (Presented before The Society for the Study of Blood at the New York Academy of Medicine, May 27, 1948).

the feature of chronic progressive anemia and correlated with it a failure of erythropoiesis without an equivalent depression of the white blood cells or platelets. Although hypoplastic anemia implies a less severe course and occasionally a more hopeful outcome than aplastic anemia, the term has, nevertheless, been applied in recent years to intermediate conditions in which the three blood elements of the bone marrow are involved in variable degree. Reports of cases of hypoplastic anemia now range from those limited to a failure of red cell production<sup>6</sup> to those in which leukocytes and platelets are simultaneously depressed but to a lesser degree than the red cells. In many of the earlier reports of congenital hypoplastic anemia, descriptions of the bone marrow<sup>7</sup> revealed a marked reduction in the number of nucleated red cells as well as an increase in the number of primitive cells or hematogones and of eosinophilic leukocytes. Estren and Dameshek<sup>8</sup> have recently described as hypoplastic anemia, familial cases with generalized quantitative hypoplasia of all the elements in the bone marrow with the nucleated red cells in normal or elevated percentages. In one of their cases of severe anemia with an increased number of reticulocytes and thrombocytopenia, splenectomy resulted in moderate clinical and hematologic improvement.

The elucidation of the factors responsible for the causation of the variety of blood disorders now included in the general category of the aplastic-hypoplastic type of anemia will be facilitated by segregating those cases which possess similar clinical and hematologic features. One group that lends itself for separate consideration concerns those instances in which the failure of hematopoiesis is restricted entirely to the erythrocytes without impairment of leukocytes or platelet production. This condition involving solely red cell production has been designated as chronic congenital aregenerative anemia by Vogel, Erf and Rosenthal,<sup>9</sup> but a more descriptive term is that of pure red-cell anemia, employed by Lescher and Hubble<sup>10</sup> who contributed 3 cases of their own. This unusual feature, in which a single cell type is depressed, constitutes the cardinal feature of this hematologic entity, and is illustrated by the following case history.

#### REPORT OF CASE

A. K. a white male infant, was born three weeks prematurely on December 28, 1946. The infant was firstborn. The delivery was normal and the infant was well for four days. At this time jaundice appeared which deepened and did not finally disappear until the third to the fourth week. At 8 days the blood count was 78 per cent hemoglobin with 3.7 M. red blood cells and the next day the values were slightly lower. No study of the blood factors was undertaken and no transfusion was given. On March 1, 1947 at approximately 2 months of age the baby developed an upper respiratory infection with a mucopurulent discharge. The child was admitted to a local hospital where a blood count revealed a hemoglobin of 29 per cent and a red count of 1.3 M. per cu. mm. One transfusion of 125 cc. of blood was given, and the child was discharged on March 4, 1947.

Both parents were healthy and there was no history of any hereditary blood disorder. There had been no preceding pregnancies.

The infant was admitted to the Children's Clinic of The New York Hospital on March 8, 1947 because of a progressive anemia.

**Physical Examination.** The infant was well developed and well nourished and in no distress. There was no jaundice; the heart and lungs were normal; the spleen and liver edge were palpable at the costal margin. There were no petechiae or other manifestations of bleeding into the skin.

**Laboratory Examinations.** The blood count on admission (table 1) revealed a hemoglobin of 9.5 grams per 100 cc. RBC 3.5 M. The white cells numbered 13,000 per cu. mm. with 25 per cent segmented

polymorphonuclear leukocytes 68 per cent lymphocytes 3 per cent monocytes and 4 per cent eosinophiles. On March 13 the hemoglobin was 8.9 grams per 100 cubic centimeters, the volume of packed red cells was

positive. The clinical course and hematologic features in the infant appeared to be similar to those of mild erythroblastosis fetalis perhaps caused in this instance by isoimmunization of an Rh positive type O mother by an A offspring. Tests of the infant's saliva showed him to belong to the nonsecretor type.\* The mother's anti-A serum titer on March 3, 1947 was 1:128,000† and on April 7 it had dropped to a level of 1:640 to 1:1280.\* At no time was anti-A agglutinin detected in the infant's serum and his red cells gave a negative Coombs test. In cases of this sort it is necessary to exclude the possibility that other rare factors may be responsible for the isoimmunization. However, antibodies in the mother's serum for the five Rh Hr antigens in bloods of type Rh<sub>1</sub>Rh<sub>2</sub> could not be demonstrated.\* Consequently, the fact that the infant was of the nonsecretor type constitutes strong support for the role of isoimmunization by the factor A.

FIG. 1.—(Patient A. K.) Smear (X850) from sternal aspiration of November 18, 1947 (see table 1) showing polymorphonuclear leukocytes, myelocytes, metamyelocytes, lymphocytes and hematogones. Note absence of nucleated red blood cells.

*Course in Hospital.* Between March 8, 1947 and November 17, 1947, there were nine hospital admissions in each instance for treatment of progressive anemia. Eighteen transfusions were given at first employing O blood to which the Witebsky A and B substances were added and later with compatible Type A Rh positive whole blood. From December 16, 1947 until the present blood has been given at intervals of approximately 3 weeks in the Outpatient Transfusion Clinic at The New York Hospital. Growth and nutrition have been normal in every respect and susceptibility to infection has not been increased. There has been no enlargement of the liver, spleen or lymph nodes.

Tables 1 and 2 summarize the more significant blood serologic and bone marrow studies. Early in the

\* These tests were carried out by Dr. Philip Levine.

† Titration by Dr. Harry Wallerstein.

course the peripheral blood revealed evidences of macrocytosis and anisocytosis, later the red blood cells were normochromic and normocytic. The hematologic data confirmed the failure of erythropoiesis without involvement of the granulocytes and platelets or their bone marrow precursors.

### DISCUSSION

From the age of 2 months, when thorough hematologic studies were initiated, until the present age of 17 months, examination of the peripheral blood and bone marrow have consistently shown that the defect in hematopoiesis was confined to a failure of red cell formation. This anemia, in which granulocyte and platelet formation are unaltered, may be rightfully termed pure red cell anemia.

The only causative factor for the anemia that can be postulated in this case is the possibly injurious effect upon fetal erythropoiesis of the anti-A agglutinin elaborated by the mother in an incompatible pregnancy. The evidence for erythroblastosis fetalis in this infant is based on the history of jaundice and anemia noted in the first week of life. The relationship of erythroblastosis fetalis to sensitization by A and B agglutinogens in Rh positive mothers has been demonstrated by many observers<sup>11-18</sup> and its occurrence in this type of immunization in the firstborn has been pointed out by Wiener.<sup>17</sup>

While the blood disorder at the onset of this patient's illness can probably be safely classified as erythroblastosis fetalis, the relationship of the anti-A agglutinin to depression of the erythropoietic centers and continuance of the anemia require further elucidation. In 2 cases observed by Wiener,<sup>18</sup> sensitization by the A B agglutinogens was associated with an aregenerative anemia. Recent studies<sup>19</sup> which relate structural defects at birth to disturbances in the fetus may possibly be extended to include fetal anomalies of blood formation originating during critical periods of hematopoietic function. It is conceivable that erythropoiesis in the fetus may be impaired by prolonged reaction with an antibody in high titer against its own red cells in the course of an incompatible pregnancy. Levine<sup>21</sup> pointed out that the A and B blood agglutinable factors can be demonstrated in the fetus between the second and third month and suggested the possibility of early isoimmunization in the first months of fetal development. It is possible, therefore, that prolonged exposure of the red blood cells and their precursors during a vulnerable period of fetal life by the anti-A agglutinin may be responsible not only for the anemia at birth but for its persistence in the neonatal period.

In the group of hemolytic anemias which includes erythroblastosis fetalis, examination almost uniformly reveals hyperplasia of the bone marrow. Potter<sup>22</sup> has pointed out, however, that in some instances the bone marrow in erythroblastosis is either normal or hypoplastic, and that the latter state may account for the progression of the anemia. Diamond<sup>24</sup> states that bone marrow hypoplasia constitutes almost a uniform complication of any severe hemolytic anemia in the newborn. After the second or third week of life the infant, even after receiving multiple transfusions, often develops a relatively aplastic stage. It should be pointed out that Shapiro and Bassen<sup>25</sup> have shown that in full-term infants a marked drop occurs normally in the erythroid elements of the bone marrow at the end of the first week of life. It would be expected, however, that except for unusual circum-

stances, the increased hemolysis characteristic of erythroblastosis should result in a hyperplasia of nucleated red cells even at one week of age. In a series of fatal cases of erythroblastosis occurring at The New York Hospital, the bone marrow was recorded as showing hyperplasia in each instance.

To test further the hypothesis that erythropoiesis may become depressed in the course of erythroblastosis fetalis, bone marrow aspiration was carried out in several instances of this disease during the period of protracted anemia. Individual examinations have shown a decreased percentage of nucleated red cells in several cases, regardless of whether treatment consisted of subtotal blood replacement or multiple transfusion. In one case in which successive bone marrow aspirations were obtained (K. H., table 3), the mother was Rh negative and the infant Rh positive. This patient was also firstborn and this circumstance could be explained by a series of transfusions received by the mother before the birth of the child. Tables 3 and 4 demonstrate the temporary depression of erythropoiesis during the progress of the anemia in which nine transfusions of blood were required to maintain normal blood levels before recovery set in.

It appears, therefore, that the temporary failure of erythropoiesis occurring in erythroblastosis may conceivably be related to the exhausting effects of persistent hemolysis in this disease, or from the suppression of the erythropoietic centers in the bone marrow or in other fetal organs of blood formation by anti-A, anti-B, or anti-Rh agglutinins in susceptible individuals. It is possible that in the case of chronic congenital aregenerative anemia described in this paper the depression of erythropoiesis may have persisted from fetal life or from the period immediately following the newborn period as illustrated in the case of K. H. It should be pointed out that the high anti-A agglutinin titer detected in the maternal serum nine weeks after the birth of the infant may be an exaggeration of the actual agglutinin titer that was operative during fetal life. Boorman, Dodd, and Mollison<sup>26</sup> have shown the peak immune anti-A isoagglutinin titer produced in the maternal serum in response to stimulation by a group A or AB foetus, was not attained in the majority of cases until ten to twenty days after delivery.

The hypothesis that a prolonged depression in red blood cell production may result from an antibody specifically directed against the red cells in fetal life or during the early neonatal period and of a sufficient intensity to produce a chronic anemia extending into later infancy and childhood requires more extensive support. It should be emphasized that the concept offered to explain the mechanism of the anemia in this case is not expected to provide a uniform explanation for the pathogenesis of all cases of this entity. Although the circumstances noted in this patient may be unique, they afford a basis for further investigation of the causation of this unusual blood dyscrasia.

#### SUMMARY

Chronic congenital aregenerative anemia describes a pure red-cell anemia in which the failure of hematopoiesis is restricted entirely to the erythrocytes without simultaneous impairment of leukocyte or platelet production. The separation of this entity from the category of the increasing number of cases designated as

hypoplastic anemia will facilitate a more direct examination of the factors involved in its pathogenesis

In the case described in this paper illustrating this condition, the onset of the anemia dated to the newborn period with the clinical and hematologic features of a mild type of erythroblastosis fetalis. The mother's blood group was O, Rh positive and that of the infant and father A, Rh positive. The anti-A serum titer in the mother reached a maximum of 1:128,000. The infant was shown to be a non-secretor. The patient, now 17 months of age, requires repeated transfusions to maintain normal blood levels. The bone marrow reveals a persistent depression of erythropoiesis but the platelet and granulocyte levels are entirely unaffected.

It is postulated that prolonged depression in red blood cell production may result from an antibody directed solely against the red cells in fetal life or from the early neonatal period. This concept finds substantiation in other cases of erythroblastosis in which temporary failure of erythropoiesis as confirmed by bone marrow studies is reflected in a state of protracted anemia.

## MEDITERRANEAN ANEMIA IN THE NEGRO

### A REPORT OF FOUR CASES AND THEIR FAMILIES

By STEVEN O. SCHWARTZ, M D , AND JACK MASON, M D

FROM an ill-defined symptom complex known as von Jaksch's anemia there emerged in 1925 a disease entity to which the eponym Cooley's anemia has since been applied.<sup>1</sup> In its classic form it is characterized by occurrence in people of Mediterranean origin, a familial incidence, mongoloid facies, splenomegaly, characteristic bone changes and bone x-ray changes, severe anemia notable early in life, and the presence of erythroblasts in the peripheral blood. Patients having Cooley's anemia usually die before the age of 12.<sup>2</sup> The condition has also been called erythroblastic anemia, Mediterranean anemia and thalassemia,<sup>3</sup> the last name apparently being quite ill chosen.<sup>18</sup>

Dameshek,<sup>7</sup> Wintrobe, Matthews, Pollack and Dobyns,<sup>24</sup> and Strauss, Daland and Fox<sup>21</sup> independently, and almost simultaneously, described a less severe form of anemia characterized principally by the presence of target cells, ovalocytes, poikilocytes, hypochromic microcytes, and stippled red cells in the peripheral blood. One of the most constant features of this condition is the increased resistance of the cells to lysis in hypotonic saline solutions. Abnormalities of the red cells may be present even in the absence of anemia and not infrequently the red cell count is higher than normal. The bones may show evidences of osteoporosis with cortical thinning. Frequently some degree of splenomegaly and jaundice are present. The names thalassemia minor, Mediterranean anemia, target cell anemia, and familial microcytic anemia have been given to this less severe form.

Originally it was felt that an important facet in the diagnosis of Mediterranean anemia was the racial origin of the patient, since the disease was thought to be limited to people of the Mediterranean basin. Abandonment of this concept is compelled, however, by the increasing number of reports describing the condition in individuals of other racial groups.<sup>26</sup> One of Cooley's original seven<sup>2</sup> cases was a mulatto child, but this case was later withdrawn by Cooley since the child's blood had an increased, instead of a decreased, hypotonic saline fragility which began at 5 per cent and was complete at 35 per cent, the child lacked the mongoloid facies and improved on a good diet.<sup>4</sup> Dameshek,<sup>8</sup> in discussing the relationship of Mediterranean target-oval cell syndromes to sickle cell syndromes, mentions a case of Cooley's anemia observed in a Negro child at the Mt. Sinai Hospital of New York. Both hematologic and bone changes were present, and repeated examinations of the blood for sickling were negative.

Lubitz<sup>16</sup> in 1945 described 9 cases of Cooley's anemia in which target cells

From the Hematology Laboratory and the Hektoen Institute for Medical Research of the Cook County Hospital, Chicago, Ill.

Aided by a grant from the United States Public Health Service for the study of the Sickle Cell Phenomenon and by a grant from the Wilson Laboratories.

occurred in the absence of anemia. The first of these was a 20 year old Negro admitted for mumps. Red cell count was 5,080,000 and hemoglobin 14.0 Gm. Hemolysis began at 0.38 per cent and was complete at 0.28 per cent NaCl solution. When repeated, the range was 0.32 per cent to 0.14 per cent. Blood films showed 67 per cent target cells with many variants, and but few normally appearing red cells, there was some anisocytosis, moderate macrocytosis and ovalocytosis. The average red cell diameter was 7.4 micra, with the target cells distributing themselves over the entire range of the Price-Jones curve. There was no evidence of active or latent sickling. The skull and long bones were roentgenologically normal. Lubitz did not consider this a case of Mediterranean anemia because of the race, but felt that it was a related condition. Stiles, Manlove and Dangerfield<sup>20</sup> reported the case of a 23 year old Negro in whom an anemia was found during an admission for pneumonia to an Army hospital. Hemoglobin values varied between 8.75 and 9.2 Gm, and erythrocytes between 4.65 and 5.33 million. Occasional basophilic stippling, target and oval cells, anisocytosis, poikilocytosis, microcytosis, and hypochromia were present. Red cell fragility ranged from 44 per cent to 18 per cent saline solution, being incomplete at the latter figure, while the control ranged from 44 per cent to 32 per cent. Urobilinogenuria was present 1:20 on three occasions. The test for sickling was negative. X-rays of the skull showed increased porosity of the parietal bones. Blood films obtained from the sister showed anisocytosis, some poikilocytosis, hypochromia, and numerous target and oval cells. The patient is described as having a typical negroid appearance, but his sister and mother, who were also treated for anemia, were very light in color. In explaining the patient's anemia the authors imply that one of the maternal great-grand parents was Italian, but offer no proof of this. Faber and Roth<sup>10</sup> describe a 6 year old Negro girl with anemia, splenomegaly and peripheral blood changes compatible with Cooley's anemia. No sickling of the red cells was demonstrable. The bone changes, while not extreme, were of a character also compatible with the disease. The only possible discrepancy was the erythrocyte fragility which was stated as beginning at 56 per cent and complete at 35 per cent, duplicating a normal control. No other members of the family were found to have any blood dyscrasias. The father and brother were in the Oklahoma state hospital for the Negro Insane. Speculation by the authors as to the origin of the patient's disease has no factual support. The case cannot be accepted as one of Cooley's anemia on the basis of the evidence presented.

It is the purpose of this communication to report a series of cases of typical Mediterranean anemia in the Negro.

#### REPORT OF CASES

*Case 1.* Julius M. This 51 year old Negro railroad porter, a bachelor, was apparently in good health until November 1945 when he was admitted to a hospital in Memphis, Tennessee, where he was told that he had pneumonia, heart trouble, and a large spleen and liver. He continued to have a cough with occasional slight hemoptysis and chest pain after being discharged from the hospital. In September 1946 he noted increasing dyspnea and swelling of his abdomen and legs, this being worst in the evening and disappearing during the night. A feeling of pressure in the left upper quadrant was present since leaving the hospital in 1945. For ten or fifteen years he had consumed an average of two quarts of wine and one to

two pints of whiskey a week. There was no history of jaundice, gastro-intestinal hemorrhage, malaria, or exposure to lead. He had been stabbed in the abdomen in 1910 and was operated at the time.

Physical findings on admission: blood pressure 180/126, pulse 120, respiration 20, temperature 99.4 F rectally. Head: typical negroid appearance with very dark skin. Eyes: sclerae muddy, no definite jaundice, pupils round and equal, react to light and accommodation. Fundi: grade II retinopathy. Ears: nose, mouth, and throat essentially negative. Neck: some venous distention. Lungs: a few basal rales on both sides. Heart: enlarged to the left with the apex beat felt in the anterior axillary line in the sixth inter-space; no murmurs, a gallop rhythm noted when he was first seen. Abdomen: somewhat distended, a left rectus scar present. Spleen: firm, lower tip 15 cm below the costal margin. Liver: firm and smooth, edge three cm below the costal margin. No palpable peripheral lymph nodes. Multiple old healed ulcers on the legs. Normal reflexes. Rectal examination was negative.

TABLE 1—Summary of laboratory findings in Case 1 and relatives available for study. Since considerable difficulty was encountered in getting the relatives to submit to studies, obvious discrepancies are present which are designated by question marks.

	Patient Julius	J. M. (twin brother)	E. M. (younger brother)	A. M. (sister)
RBC	5.2 (average)	6.26	5.39	5.59
Hgb	71% (average)	113% (?)	87%	89%
Hematocrit	40%	43%	42%	40%
WBC	9,000	6,550	7,950	8,000
Nucl. RBC	1 to 2/100 WBC			
Target cells	90% or more	Very many	Approx. 50%	Occasional
Macrocytosis*	Present		Present	
Hypochromia	+++	++	+	
Poikilocytosis	Present		Present	
Anisocytosis	+++	++	++	
Reticulocytes	1 to 5%	1.1%	Less than 0.5%	0.4%
RBC fragility	0.36% to 0.01%	0.42% to 0.20%	0.55% to 0.24%	0.46% to 0.15%
Sed. rate	0 mm./hr.	0 mm./hr.	8 mm./hr.	12 mm./hr.
Sickling	Negative	Negative	Negative	Negative
Serum bilirubin	1.4 mg %	6 mg %	4 mg %	1.0 mg %
Serum iron	0.60 micrograms	0.55 micrograms	0.25 micrograms	0.30 micrograms
Urine				
Urobilinogen	++	++	+	Trace

\* Macrocytes noted were large thin cells.

Question marks refer to questionable findings which could not be rechecked.

Urine: albumin ++, sugar negative, specific gravity 1.014, urobilinogen ++ (repeatedly). Blood counts: see table 1. Total protein 7.3 Gm per 100 cc, with 4.3 Gm albumin and 3.0 globulin. Icterus index 9, NPN 29. Total cholesterol 210 mg per cent. EKG: Left axis shift. Abnormal graph compatible with coronary insufficiency. X-ray of the chest essentially negative. X-rays of femur, humerus, and hands—within normal limits. The skull had a few small discrete round, radio-luencies which are presumably due to Pachionian bodies. Multiple myeloma was considered a remote possibility. The marrow obtained by sternal puncture was found to be moderately cellular; megakaryocytes were present in adequate numbers and appeared to be normal; nucleated RBC:WBC ratio was about 3:2; erythropoiesis was normoblastic and showed a right shift; granulopoiesis was intact. The findings were compatible with regeneration secondary to active chronic hemolysis.

The diagnoses of (1) hypertensive heart disease with decompensation and (2) hemolytic anemia (Mediterranean type) were made.

The patient received ammonium chloride, thiamin, hykinone, glaucophyllin, and ferrous sulphate during his stay. He gradually became compensated and was discharged to the clinic with instructions to take a high protein diet, brewer's yeast, and digitalis.

*Patient History and Physical Findings of Parents and Siblings (fig 1)* As far as the patient knew his father was a full blooded Negro who died at the age of 89. The mother was brown skinned, and possibly had some Indian blood. There were 9 siblings. Five had died: one at the age of 2 and one at the age of 6 of causes unknown, the third died at the age of 26 of pneumonia and did not seem to be the right color when he died, the fourth died at the age of 32 of malarial fever following a few weeks illness, the fifth died at the age of 46 of pneumonia. Three of the living siblings were examined.

J. M. Jr. age 51, a nonidentical twin of the patient. He was of a much larger and heavier build and had been a prize fighter in his youth. Questioning revealed that his eyes had been yellow when he was younger, but he had attributed it to the trauma of prize fighting. He was married. His three children were dead. One died at the age of 3 of colic, one at 5 of pneumonia, and third at 6 of a cold. Physical examination was nonrevealing.

E. M. age 45, male, no pertinent history, had one son, age 25, in the Army. Physical examination was nonrevealing.

A. M. age 34, female, had no children. Her history and physical examination were without significance.

One sister lived out of town and was unavailable for study.

Blood findings are noted in Table 1.

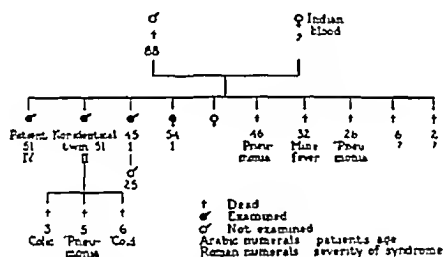

FIG. 1.—GENEALOGIC HISTORY OF CASE 1

The roman numerals refer to the type and severity of the individual's Mediterranean anemia. The classification is that of Dameshek and Limentani (table 5).

*Comment* The patient had no symptoms referable to his anemia. He presented himself because of cardiac decompensation, on the basis of a hypertensive cardiovascular disease. As in other types of hemolytic anemia numerous ulcers (healed) were present on the legs.<sup>9</sup>

No known Caucasian or Mediterranean admixture was present in the family. Of the four siblings examined, the patient had the most severe form of the disease, the nonidentical twin a less severe form, the younger and older siblings a still milder form. Whether the death of the siblings or the early death of the brother's three children had any relation to the disease under discussion is purely problematic.

*Case 2* Frank F. This Negro male was first seen in March 1941 (age 24) because of a cellulitis of the arm. A large hard spleen extending 4 cm. below the costal margin was found. The only other abnormal physical findings were small bilateral inguinal slightly enlarged axillary and palpable cervical lymph nodes. The liver was not enlarged.

The patient was born in Louisiana and lived there the first 20 years of his life. He had had fever at the age of 12 or 13 for which he had taken 666 and quinine. In 1940 he had a single chill but was able to return to work the following day. He used alcoholic beverages in moderation.

No malarial parasites were found after repeated adrenalin injections. The blood showed 63 per cent

(9.8 Gm) Hgb 3.95 RBC, 7,400 WBC, 74 polys (6 bands) 24 lymphocytes 1 monocyte 1 metamyelocyte. The red cells showed polychromatophilia ++ hypochromia + anisocytosis +, poikilocytosis +, with macrocytes present. The reticulocytes numbered 14 per cent and a rare nucleated red blood cell was seen. Wet preparations were negative for sickling. Hemolysis of red cells began at 0.38 per cent NaCl solution and was incomplete at 0.12 per cent. Urinalysis revealed no sugar or albumin. NPN 41 mg creatinine

TABLE 2.—Summary of hematologic findings in Case 2 and family

	Hgb	RBC	WBC	Retics	Target cells	Aniso	Hypo	Micro	Saline Fragility	Remarks
Frank F (patient)	83% average	5.10 average	7,500 average	5%	Almost 100%	+++	++		0.38% incomplete at 0.20%	Occ. nucleated red cells

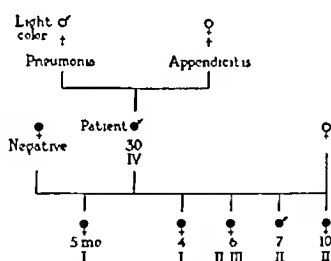

FIG. 2.—GENEALOGIC HISTORY OF CASE 2

The symbols are similar to those used on figure 1

1.3 mg. Sternal marrow was slightly hypercellular with a proliferation of the erythroid series. Discharge diagnosis was splenomegaly of unknown origin.

He was readmitted in September 1947. He had been working and well between admissions. In August 1947, however, he began to notice a dull ache in the left upper quadrant where he could feel a mass. The ache was brought on by a long walk or exercise and disappeared after a few minutes of rest. It was unrelated to meals and he felt as strong as ever before. Examination revealed a tall robust Negro with no significant physical findings other than the enlarged spleen which was felt nine cm. below the costal margin. The urine contained ++ to +++ urobilinogen. Kahn test was negative. Hematologic findings are shown in table 2. Serum bilirubin 1.35 mg. per cent. sedimentation rate 3 mm. per hour. hematocrit

43 per cent. The marrow was quite cellular, megakaryocytes were qualitatively normal but their number was relatively decreased, nucleated RBC/WBC ratio approximately 3:1, normoblastic erythropoiesis, large numbers of lymphocytes. The findings were again interpreted as compatible with chronic hemolytic anemia.

The patient's father died of pneumonia when the patient, an only child, was about ten years old and his mother died shortly afterward of appendicitis. He had been brought up by his paternal grandmother who was light brown and he remembered that his father was light too. He had 4 living children by his first wife, and one by the second (10, 7, 6, 4 years and 5 months). All the children were examined and none had abnormal physical findings. Sickling of the red cells could not be demonstrated in either the children or the second wife. The results of the hematologic studies are charted in table 2. One child (the third) had almost 100 per cent target cells and a slightly increased resistance to hypotonic saline solution (0.42 to 0.15). The second wife's blood was normal excepting for a slight iron deficiency. Both of the older children had a slight iron deficiency. Both of the older children had a slight erythrocytosis and the presence of target cells while the two youngest showed only target cells (fig. 2).

*Comment.* In spite of a fairly severe form of Mediterranean anemia this patient was never significantly incapacitated by his disease. Whether Mediterranean admixture was present is questionable, but that this is a possibility is suggested by the fact that the patient's father was light and the grandmother light brown. All the patient's children had mild forms of Mediterranean anemia, though the second wife was free of the trait as presumably was the first.

*Case 3.* Lillian N. This Negro female was born on April 18, 1935. In 1939 she was admitted to an other hospital because of an acute illness and upon recovery was discharged with the diagnoses of acute tonsillitis and pharyngitis, suppurative otitis media and sickle cell anemia.

In July 1942 she entered the Cook County Hospital with the admitting diagnosis of blood dyscrasia. Her presenting symptom was epistaxis of a week's duration. She had been having nosebleeds from time to time for two or three years but they had become more severe during the preceding year. There were no other complaints. She had had whooping cough at the age of 3, chicken pox at 4, and measles at 5. The only physical findings of significance were a systolic murmur at the apex of the heart and a freely movable enlarged spleen. Laboratory data: icterus index varied between 21-25, NPN 39, urines were negative for sugar, albumin and cells. X-rays of the skull showed considerable bony thickening with numerous sclerotic striations extending at right angles to the tangential line. These striations were particularly marked in the occipital area. There were also marked changes in the texture of the bones of the forearm and legs. The diagnostic possibility of Cooley's erythroblastic anemia was suggested. The blood counts are assembled in table 3. EKG was normal and showed a left axis deviation. Marrow at this time was reported as showing an erythroblastic proliferation compatible with a hemolytic process.

The patient's nosebleeds were few while she was in the hospital and she was discharged without specific therapy or a definite diagnosis.

She was readmitted in January 1946 with the diagnosis of splenomegaly. There was a history of chills, fever, jaundice, weight loss and headaches for one week. A slight jaundice, splenomegaly and a blowing systolic murmur over the base of the heart were found at this time. Laboratory data: Wassermann test negative, urine urobilinogen 0 to +++, total proteins 7.8, albumin 4.2, globulin 3.6, icterus index 13. Red cell fragility showed partial hemolysis at 30 per cent and was complete at 22 per cent. X-ray

The views of the tibiae, fibulae, radii, ulnae, carpals and proximal metacarpals show the following changes which are most marked in the metacarpals: thinning of the cortex, great prominence of the trabeculae, decalcification which is greatest in the spongiosa, some widening of the shafts of the bones especially in the metacarpals. The findings are probably all on the basis of hyperplasia of the bone marrow. Four views of the skull reveal marked atrophy of the outer table and generalized radial striations. The pictures are most like those described for erythroblastic (Cooley's) anemia although similar changes have been described in sickle cell anemia.<sup>11</sup> EKG: Rate 100, sinus rhythm, P-R interval 0.12 second, QRS 0.6 second, QRS upright in I and II, QRS<sub>3</sub> is notched and diphasic, S<sub>2</sub> present and T<sub>2</sub> inverted. Abnormal curve indicates myocardial damage. She was discharged as a case of sickle cell anemia.

In December 1947 she was seen in the Anemia Clinic. Physical examination revealed slightly icteric sclerae pallor of the mucous membranes and small shotty cervical, axillary and inguinal lymph nodes. The liver was felt 4 cm and the spleen 9 cm below their respective costal margins. A systolic murmur, most marked at the pulmonic area was heard over the precordium. Laboratory data +++ urobilinogenuria thymol turbidity 5.7 units stools negative for parasites blood negative for malaria. Sternal marrow aspiration revealed a very hypercellular marrow the megakaryocytes were relatively decreased nucleated RBC WBC ratio approximately 20:1, normoblastic erythropoiesis with a right shift intact granulopoiesis. X rays of the skull and long bones, as before, were typical of Cooley's anemia.

TABLE 3 — *Summary of representative blood counts obtained over a five year period in Case 3. It is to be noted that except following transfusions, she always appeared (pseudo) iron deficient and never showed sickling of the red cells*

The parents and siblings were examined as far as possible. The data are presented in Table 4.

The father and mother were both typically negroid in appearance. They were both about six feet tall and very well developed. Neither was jaundiced or had a splenomegaly. On the basis of the blood studies however they both had Mediterranean anemia.

The oldest child (D. N. male 16 years) had been diagnosed as having congenital heart disease at the age of 3. He had a to and fro murmur at the second left interspace with a rough systolic murmur at the apex. The blood picture was diagnostic of Mediterranean anemia.

The second child (G. N. male 14 years) had no abnormal physical findings. The blood findings however were those of Mediterranean anemia.

The patient (L. N. third child) had a severe anemia. blood and urine evidence of active hemolysis.

bone findings compatible with Cooley's anemia, hepatosplenomegaly, and stunting of growth. She is an example of Cooley's anemia.

The fourth child, (D, female, 10 years), had the same general appearance as her sister L. N. Prior to her birth, the mother had contracted syphilis and the child had been diagnosed as a congenital luetic. She was treated until the age of 9, when therapy was discontinued though her serologic tests for syphilis were still positive. She had a 'tower skull', hepatosplenomegaly and marked evidence of blood regeneration. She was also an example of Cooley's anemia.

The fifth child (W. N. male, 8 years), showed some target cells and an increase in urinary urobilinogen. No enlargement of the spleen or liver were demonstrable. Venipuncture was not allowed. This case represents the mildest form of red cell aberration seen in Mediterranean anemia.

The sixth child (R. N. female, 4 years) showed 30 per cent reticulocytes, some anisocytosis and hypochromia. The liver was felt 1.5 cm. below the costal margin but the spleen was not felt. Because no further studies could be performed it is not possible to ascribe definite significance to the high red count and low hemoglobin but in all probability this was a mild case of Mediterranean anemia. Data on the seventh and eighth children are insufficient for definite diagnoses. The blood film of the eighth child was however suggestive of Mediterranean anemia with great numbers of large thin cells, some target cells and anisocytosis being present. Both children had disproportionately high red cell levels for the hemoglobin values (fig. 3).

No history of exposure to lead or history of symptoms referable to lead poisoning, could be obtained from any of the family.

*Comment:* This patient had a typical Cooley's anemia as did a sister two years younger. As would be expected, on the basis of the assumption that this condition represents a homozygous trait, both parents showed evidences of a mild form of Mediterranean anemia. The other 6 siblings all had some stigmata of Mediterranean anemia. No evidence of Mediterranean admixture was found.

The patient (L. N.) and her sister (D. N.) were somewhat older and in much better clinical condition than the usual case of Cooley's anemia. However, Wolman and Dickstein<sup>26</sup> in their review of Mediterranean anemia list a number of reports of patients with moderately severe anemias and marked hematologic abnormalities, many of whom also had clinical and roentgenologic findings and yet survived beyond adolescence, and Daland and Strauss<sup>6</sup> report a case who survived to the age of 20 and gave birth to a viable child (who has Mediterranean anemia).

*Case 4 Frank D.* This 26 year old Negro male was first admitted to Cook County Hospital in July 1946 because of headaches, malaise, fever (six days), cough (two days), dyspnea (one day), and pain in the left chest especially when coughing (one day). Blood pressure 105/60, pulse 100, temperature 105.2 F, respirations 40. There was increased tactile fremitus, impaired resonance and bronchial breathing over the right lower lobe. The postauricular and inguinal lymph nodes were slightly enlarged. X-ray of the chest revealed only a prominent pulmonary conus. Kahn test was negative. The blood count, together with the count of the second admission is shown below. He was treated with penicillin and ferrous sulfate. His discharge diagnosis was broncho-pneumonia.

His second admission was in December 1947. This time he had a cold for two weeks with cough and fever and an urticarial rash for one day. There was no history of exposure to lead or of blood loss and the diet was adequate. His temperature was 102 F, respiration 24, pulse 120. He was well developed and acutely though not seriously, ill. The sclerae were slightly jaundiced. Small (0.5 cm.) bilateral discrete cervical nodes, a small (1 cm.) right epitrochlear, and discrete fairly firm inguinal nodes (3 cm.) were felt bilaterally. The liver was just palpable in the epigastrium. The spleen was firm and was palpable eight cm. below the costal margin.

Laboratory findings on this admission were as follows: ++++ urobilinogenuria, no glycosuria or

TABLE 4.—Summary of the laboratory findings in the family of Case 3. In this family both parents had mild Mediterranean anemia and therefore some evidence of the disease is expected to be present in 75 per cent of the offspring

Sternal marrow aspiration on December 12, 1947 revealed a very cellular marrow megakaryocytes were present in adequate numbers and appeared normal nucleated RBC WBC ratio was approximately 5:1 Erythropoiesis was markedly accelerated normoblastic in character and showed a left shift, mitotic figures in the erythroblast series were numerous granulopoiesis was not remarkable there was a moderate increase in plasma cells

**Family history** The patient was one of 11 children. He had an older brother in Chicago who was examined. Another brother had been killed in a train accident and one brother had died of liver disease. The mother and 7 sisters were living away from Chicago and were therefore unavailable for study. The father who was said to have been very light in color died (cause unknown) many years ago. Neither the patient nor his brother knew whether any of the sisters had been jaundiced or anemic. The brother's blood revealed RBC 5.69 Hgb 103 per cent WBC 14,150, reticulocytes 1.0 per cent hematocrit 43 per cent, urine urobilinogen + Serum bilirubin reported as 0. Fragility of the red cells began at 44 per cent NaCl solution and duplicated the normal control in the lower range. No enlargement of the liver or the spleen were demonstrable.

**Comment** The blood and marrow findings, the jaundice and the splenomegaly are diagnostic of a severe Mediterranean anemia. The brother (only sibling examined) does not have the disease (fig 4). Unfortunately, no one else in this large

family could be studied. What the father's light color signifies, as far as Mediterranean admixture in the patient's ancestry is concerned, is problematic.

FIG. 4.—GENEOLOGIC HISTORY OF CASE 4  
The symbols are similar to those used on figure 1

### DISCUSSION

Cooley's anemia is the severest form of an aberration in red cell production and/or hemoglobin synthesis known as Mediterranean anemia. The mild form may be considered as being heterozygous for the trait, which is transmitted as an incomplete dominant factor<sup>6, 11, 17, 21, 22</sup> and whose presence can be demonstrated by hematologic studies. The severe form of the disease (Cooley's anemia) represents the homozygous form inherited from both parents. This is well exemplified in Case III. This relationship is not dissimilar to that occurring in sickle cell disease and sickle cell disease.

The shading from normal to Cooley's anemia is gradual and can be arbitrarily subdivided into mild, moderate, or severe forms or even into smaller groups, as suggested by Dameshek.<sup>6</sup> We have found his classification, which is reproduced here as table 5, quite useful, although intermediate forms and shadings from one group to the other occur no matter how small the subdivision. It soon must become obvious to those studying these cases that one must think of these conditions as more or less inconstant, rather than as arbitrarily fixed and readily pigeonholed.

The increasing number of reports dealing with the finding of sickle cell in Mediterranean peoples<sup>13</sup> and, on the other hand, the apparently not uncommon finding of Cooley's and Mediterranean anemias in Negroes, as indicated in this communication, leads to interesting speculation as to the consequences of the intermarriage of persons with sickle cell anemia and Mediterranean anemia. The two patients reported by Haden and Evans<sup>14</sup> may have been the offspring of such a union. They were of Sicilian descent, had anemia, splenomegaly, and sickling. Since they were 15 and 21 years of age, the presence of splenomegaly makes one especially suspicious of such possibility since marked splenic enlargement after the age of 7 in sickle cell disease is very uncommon.<sup>1</sup>

It is also worthy of speculation what the results of the crossing of other types of hemolytic anemias, with either Mediterranean or sickle cell anemias, would be. For example, we have recently seen a case of congenital hemolytic anemia in a Negro (11 other cases having recently been collected by Goodman and Cates<sup>15</sup>). What the result of the crossing of this disease with the above mentioned ones

would be is problematic and only the careful study of the families of all cases of atypical hemolytic disease will help clarify this problem

It is interesting, in retrospect, to note how often the diagnosis of sickle cell anemia had been made in our patients, notwithstanding the fact that sickling of the red cells was never demonstrated. However, it might even be conceivable that sickling of the red cells might be considered present in some cases, since in the moist chamber the naturally occurring poikilocytosis could, by the inexperienced, be mistaken for sickling. The number of these pseudo-sickle cells, however, does not increase even on prolonged standing.

The differential diagnosis between sickle cell anemia and Mediterranean anemia may be extremely difficult or even impossible on clinical grounds, and may depend entirely on the demonstration or lack of demonstration of sickling. The great

TABLE 5—Types of Mediterranean anemia (classification of Dameshek and Lawrence). It is to be noted that these divisions are arbitrary and overlapping between groups and findings is common.

	Hgb	Target oval or stippled cells	Spleno- megaly	Jaun- dice	Bone changes	Nucleated red cells
	%					
1 Congenital lepto and elliptocytosis	80+	+	o	o	—	—
2 Hypochromic erythrocytosis	80+	++	o	o	—	—
3 Hypochromic anemia	65-80	++	o	o	—	—
4 Hypochromic erythrocytosis with splenomegaly	65-80	++++	+	+	—	—
5 Congenital hemolytic target oval cell jaundice	50-65	++	++	+	+	—
6 Adult anerythroblastic type of Cooley's anemia	Less than 50	+	+++	++	++	—
7 Cooley's erythroblastic anemia	Less than 40	+	++++	++++	++++	++++

The common denominator of all the above types is the decreased hypotonic fragility, the presence of target and oval cells, and the lack of response to iron therapy.

similarity of the two conditions is emphasized in table 6. Whether these similarities imply an ethnologic or anthropologic relationship, we are unprepared to say, but the geographic proximity of the roots of these conditions certainly suggests such a possibility.

Malaria, especially in those patients who had spent some time in the South (as cases 1, 2, and 4) must be considered in differential diagnosis especially in view of the jaundice and splenomegaly. This condition was ruled out by careful examination of both blood films and marrows.

We were impressed by the excellent general health (with the exception of Case 3 and her sister with Cooley's anemia), the robust appearance, and the relative paucity of both ancient and recent history of illness which might have called attention to the underlying condition in this group of patients. This serves to underline the necessity for not only awareness but also of constant search for the

TABLE 6—Comparison between clinical and laboratory findings of sickle cell and Mediterranean anemias, showing for the most part, striking parallelism in the two conditions

	Sickle cell		Mediterranean anemia	
	Anemia	Trait	Cooley's anemia	Trait

disease. By virtue of the partial dominance of the gene it is safe to assume that we are dealing with a condition whose recognition will henceforth occur more and more frequently.

We wish to re-emphasize the dictum previously advanced<sup>19</sup> that even though our patients had the typical negroid appearance of skin, hair, facies, etc., Caucasian admixture cannot be ruled out. This aspect of the problem is entirely academic, since the North American Negro is admittedly a hybrid group, but none-the less represents the type of patient in whom we are interested. Whether the condition exists among unmixed Negro races remains to be answered by those who have access to this type of material.

### SUMMARY

Four cases of Mediterranean anemia are reported in Negroes.

The hematologic and clinical findings of available relatives are presented.

The disease in the Negro resembles the condition as found in people of Mediterranean ancestry in every particular.

# A RAPID SLIDE TEST FOR HETEROPHILE ANTIBODY IN INFECTIOUS MONONUCLEOSIS

By WILLIAM C. MOLONEY, M D, AND LUCY MALZONE

SINCE the discovery by Paul and Bunnell<sup>1</sup> in 1932 of the presence of heterophile antibodies in the sera of patients with infectious mononucleosis, there has been a great deal of investigation into the nature and production of anti-sheep red cell agglutinins.<sup>2</sup> With the advent of the Rh factor and the subsequent discovery of blocking<sup>3</sup> (incomplete,<sup>4</sup> or hyperimmune<sup>5</sup>) antibody new avenues of approach were opened to many perplexing problems concerning red cell antigenicity.

In 1945, Levine and Gilmore<sup>6</sup> reported the discovery of a blocking antibody in the serum of a patient with infectious mononucleosis. At this time attempts by one of us (W. C. M.) to disclose heterophile blocking antibody, using sheep and goat cells, were unsuccessful.<sup>7</sup> However, this work was carried out in England while in the Army Medical service and comparatively few cases were studied, moreover, the proper breed of goat was not obtainable. When knowledge of Diamond's slide method for Rh testing became available in June 1945, a modification of this test was employed to further search for the presence of blocking antibody in the sera of cases of infectious mononucleosis and other diseases. For the past three years this work has been carried out more extensively in civilian practice and since the slide method may have practical applications, its use is reported in this paper.

## METHODS AND MATERIALS

The test was carried out by mixing 0.1 cc. of defibrinated sheep blood on a glass slide with 0.2 cc. of serum to be tested. Tests were considered positive only if 3 plus to 4 plus macroscopic clumping occurred within 30 to 60 seconds. The heterophile antibody test was carried out on the same sera using the Paul Bunnell method.<sup>1</sup> A serum dilution of 1:128 was considered the lowest positive level. The sheep cells were preferably used fresh but defibrinated sheep blood kept at 5°C for two weeks gave reliable tests. Citrated, phenolized and 50 per cent saline sheep cell suspensions also gave good results with strongly positive sera. However, to avoid factors which might interfere with blocking antibody only defibrinated sheep blood was used in the slide tests reported in this paper. Serum was obtained in the usual fashion. Inactivation was carried out in a number of cases but for practical purposes this was found to be unnecessary. Sera kept in the icebox lost potency slowly while if stored in the deep freeze the heterophile antibody content was well preserved for long periods. The amounts of serum and cells used in the test made a definite difference in the agglutination reaction. A 2 to 1 proportion of serum to cells was found to give the most clear-cut test. All slide tests were carried out at room temperature. As described below the heterophile antibody in infectious mononucleosis is active at 37°C as well as at lower temperatures. In certain cases of cirrhosis and patients with hemolytic syndromes the antibody which gave a positive slide test at room temperature was inactive when the test was carried out at 37°C.

---

From the Clinical Research Laboratory, Holy Ghost Hospital, Cambridge, Massachusetts and the Departments of Medicine and Pathology, Tufts College Medical School, Boston, Massachusetts.

Paper read at the annual meeting of the American Federation for Clinical Research, Atlantic City, N. J., May 4, 1948.

In part this study was supported by a grant from the American Cancer Society (Massachusetts Division).

## RESULTS

Tests were carried out on the sera of 473 individuals with various diseases and in this group were included a number of normal controls

*Infectious Mononucleosis* In this group there were 41 patients with definite hematologic and clinical evidence of the disease (see table 1)

Of these 41 cases, 34 were serologically positive by the Paul-Bunnell test at some time during the course of the illness. There were 6 cases in which repeated heterophile antibody titers were 1:8 or below and the slide tests were also negative in these individuals. In one case the heterophile antibody titer was 1:64 and at the same time the slide test was positive, otherwise the remaining 34 cases had titers of 1:128 or above with strongly positive slide tests. It was observed that in

TABLE 1.—*Infectious Mononucleosis*

Diagnosis	Total cases	Positive slide test	Positive Paul Bunnell test
Infectious Mononucleosis	41	35	34

TABLE 2.—*Diseases of the Liver*

Diagnosis	No. of cases	Positive slide test	Positive Paul Bunnell test
Cirrhosis (Laennec)	43	6*	0
Cirrhosis (biliary)	5	0	0
Cirrhosis (post infectious hepatitis)	5	1*	0
Acute infectious hepatitis	21	0	0
Total	74	7	0

\* Positive at room temperature, negative at 37 C.

following the disease along, as the heterophile titer in saline fell below 1:128 the slide tests became negative.

*Diseases of the Liver* The sera of 53 patients with cirrhosis of the liver and 21 patients with acute infectious hepatitis were tested (see table 2.)

In 6 cases of cirrhosis of the Laennec type and one of cirrhosis following infectious hepatitis, positive slide agglutinations of sheep cells occurred. However, in none of these cases were sheep cell agglutinins by the Paul-Bunnell method present in a dilution of 1:8 or above. On carrying out the slide test at 37 C, the agglutination disappeared. This is in contrast to the sheep cell agglutinins found in infectious mononucleosis which are active at 37 C as well as lower temperatures. It was concluded that the sheep cell clumping observed on the slide at room temperature in these cases was due to nonspecific cold agglutination.

Although most of the cases of infectious mononucleosis in this series gave positive cephalin-cholesterol flocculation, thymol turbidity and ZnSO<sub>4</sub> turbidity tests, there was no apparent correlation between the presence of heterophile anti-

body (either by slide test or by the Paul-Bunnell method) and the occurrence of these tests which indicate an alteration of the serum proteins. In keeping with the observation of others, positive heterophile antibody tests were not found in the cases of infectious hepatitis.

*Malignant Diseases* The sera of 58 patients with a variety of neoplastic disorders were examined for heterophile antibodies (see table 3).

In only one case was a positive slide test observed. This occurred in a patient with multiple myeloma but subsequently repeated tests on the same patient were negative. Sera from other patients with multiple myeloma have shown no increase in heterophile antibodies nor have slide tests been positive.

TABLE 3.—*Malignant Diseases*

Diagnosis	No. of cases	Positive slide test	Positive Paul Bunnell test
Cancer	40	0	0
Malignant lymphoma	5	0	0
Leukemia	7	0	0
Multiple myeloma	6	1*	0
Total	58	1	0

TABLE 4.—*Normal Pregnancy and Cord Blood*

Diagnosis	No. of cases	Positive slide test	Positive Paul Bunnell test
Pregnancy	95	0	0
Cord blood	23	0	0
Total	118	0	0

*Normal Pregnancy and Cord Blood* The sera of pregnant women may show various positive flocculation tests. However, in 95 patients during pregnancy and in 23 cord blood specimens there were no positive heterophile antibody tests (see table 4).

*Hemolytic Disorders and Iso-immunized Women* This group of patients deserves special consideration and further studies are being carried out (see table 5).

In 7 patients with acquired hemolytic anemia there were 2 cases which gave positive slide tests. These 2 individuals had no increase in heterophile antibody by the Paul-Bunnell test. When the slide test was carried out at 37°C, no agglutination occurred. These two patients had very strong cold autohemagglutinins. Both had undergone splenectomy without improvement and subsequently one patient died and was found to have a bizarre myeloblastic leukemia. The other patient survived but has continued to show hemolytic anemia and no further underlying disease has been disclosed to date.

In the sera of 10 women heavily immunized in pregnancy by the Rh factor there were no heterophile antibodies found. There were 3 women strongly immunized

by fetal A<sub>1</sub> cells and one woman with anti-B agglutinins giving a positive serum dilution of 1:60,000. In none of these women were there positive heterophile antibody tests. However, a patient who is still under investigation has been of considerable interest. After this woman gave birth to her second baby the infant developed moderately severe hemolytic disease. The mother was O, Rh positive, the father was also Rh positive, A<sub>1</sub> A<sub>2</sub>—and the infant was A<sub>2</sub> O, Rh positive.\* The mother developed an Anti A<sub>2</sub> agglutinin which reached a positive dilution of 1:50,000. This serum also gave a positive slide test for heterophile antibody which did not disappear at 37°C and the Paul-Bunnell test showed a borderline

TABLE 5—*Hemolytic Syndromes and Iso-immunized Women*

Diagnosis	No. of cases	Positive slide test	Positive Paul Bunnell test

positive dilution of 1:64. On absorption tests the antibody was absorbed by guinea pig kidney but not by boiled beef cells. This antibody was apparently related to the Forssman type rather than the variety of sheep cell agglutinins found in infectious mononucleosis.

*Miscellaneous Diseases and Controls.* Tests were carried out on the sera of patients with a variety of diseases. In this group were included 3 cases of serum sickness. None of these had positive heterophile tests although it should be expected that if strong enough, the heterophile antibodies of the Forssman type would give positive slide tests. Unfortunately, the only tests on these three cases were carried out on the 1st or 2nd day of the illness and later specimens of serum were not obtained for testing (see table 6).

In the sera of 110 normal individuals, there were no false positive tests.

\* The genotypes and specificity of the anti A sera were kindly determined by Dr. William Boyd of Boston University Medical School.

## SUMMARY AND CONCLUSIONS

The sera of 473 individuals were examined for sheep cell agglutinins both by the slide test and the Paul-Bunnell method. In this group there were 46 patients with positive slide tests and 35 of these individuals also had a diagnostic serum dilution test for heterophile antibody. In 11 cases the slide test was positive but the Paul Bunnell test gave very low serum dilution values. However, when the slide test was carried out at 37 C, it was negative in 9 of the 11 cases. In the remaining 2 instances, one patient had a Forssman type of antibody which gave a 1:64 titer in saline and the slide test was positive at 37 C. In the other case no studies were made on the effect of temperature and the nature of the agglutination reaction was unfortunately not determined.

Using human and bovine albumen, sheep serum and human AB serum absorbed with sheep cells as a diluent no evidence for blocking or hyperimmune antibody was discovered in the cases of infectious mononucleosis studied in this series. Moreover, of the 6 patients with negative serology but with strong clinical and hematological evidence for the disease, no blocking or hyperimmune antibody was disclosed by the slide test or by the use of absorbed human AB serum. The conclusion seems justified that blocking, incomplete or hyperimmune heterophile antibody must be rather uncommon in infectious mononucleosis.

In the use of the rapid slide test it has been pointed out that cold agglutinins, (which may be abolished by warming to 37 C) and Forssman antibodies (which may be absorbed by guinea pig kidney) can give positive results. However, diseases in which cold agglutinins are strong enough to give a positive slide test are relatively rare and the occurrence of Forssman antibodies of a strength likely to give a positive slide test would be decidedly uncommon. In any event unless further experience reveals more serious discrepancies, the rapid slide test as described in this paper seems to offer a practical screening test to detect clinically significant amounts of heterophile antibody in cases of infectious mononucleosis.

# THE PARALLEL EFFECTS OF MAGNESIUM ON THE COMPLEMENTARY AND COAGULATIVE ACTIVITIES OF BLOOD SERUM

By FRANK MALTANER, PH D, AND JOSÉ O DE ALMEIDA, M.D

THE CLOSE relationship between the role of calcium in the clotting and complement activities of serum has already been shown.<sup>1</sup> More recent studies have demonstrated the effect of magnesium in the hemolytic activity of complement<sup>2</sup> and in the clotting reaction.<sup>3</sup> Since it is well known that magnesium salts do not replace calcium in the clotting process, this work suggested that the part of magnesium be further explored. It has been found that the effect of magnesium ions in both phenomena is parallel, either alone or in the presence of such antagonists as human serum and disodium phosphate. The practical importance of ionized magnesium salts in complement-fixation tests has also been emphasized by other investigators.<sup>2</sup> Experiments were therefore made to determine whether addition of these salts affects the quantitatively standardized complement-fixation procedure developed in this laboratory.

## MATERIALS AND METHODS

Complement was obtained from frozen pools of guinea pig serum used in routine complement fixation tests.<sup>4</sup>

Inactivated human serum was a pool of sera inactivated at 56 C. for one half hour prior to use.

Disodium phosphate was prepared by diluting 1/10th molar solutions with physiologic salt solution.

Magnesium chloride and calcium chloride were similarly prepared from molar solutions of these salts.

Cephalin was phosphatidyl serine prepared by the method of Folch,<sup>5</sup> further purified by reprecipitation from hot methyl alcohol,<sup>6</sup> and dissolved in petroleum ether. It was suspended in distilled water from the dried state as 0.1 per cent solution, was dialyzed overnight, made isotonic, and, diluted 1:10 with physiologic salt solution.

Dioxalated plasma,<sup>7</sup> used for titration of prothrombin activity, was prepared from cell free 0.1 per cent oxalated plasma obtained by the carotid bleeding of guinea pigs using paraffined canulae and tubes chilled in ice. Nine volumes of blood were collected in one volume of 1 per cent sodium oxalate dissolved in 0.5 per cent sodium chloride. After removal of blood cells at low speed the plasma was transferred to paraffined tubes and the platelets removed as completely as possible by high speed centrifugation for one to two hours in the refrigerated centrifuge. The horizontal position in the centrifuge should be used and the time required depends on the speed available. A plasma that clots in ten minutes or longer in glass tubes and after optimum recalcification may be used but much more stable plasma is obtainable by these procedures. The dioxalated plasma was prepared by diluting oxalated plasma with four volumes of 0.1 per cent sodium oxalate in physiologic salt solution.

The hemolytic system was prepared from washed 5 per cent sheep cells and antisheep cell amboceptor.<sup>4</sup>

## Clotting Technic

The quantity of complement selected for use in clotting tests was one unit as employed in the quantitatively standardized complement-fixation test for syphilis, 1 c, the amount required for 50 per cent hemolysis of a standard dose of maximally sensitized sheep cells in fifteen minutes in a water bath at 37 C. Amounts of calcium

From the Division of Laboratories and Research, New York State Department of Health, Albany, N. Y.  
Presented at the meeting of the American Association of Immunologists, March 17, 1948, Atlantic City, New Jersey.

chloride and cephalin were used that, when incubated for six minutes in preliminary titration with one unit of complement in a total volume made up to 0.6 ml with physiologic salt solution, clotted 0.1 ml of added dioxalated plasma in ten minutes. In the experiments recorded below, this corresponded to 0.1 ml of  $M/400$  calcium chloride and 0.1 ml of 0.01 per cent phosphatidyl serine.

In the tests of the inhibiting effect of inactivated human serum and disodium phosphate and of the enhancing action of magnesium chloride, varying amounts of these reagents were pipetted into the test tubes followed by complement, calcium chloride, cephalin, and physiologic salt solution to a volume of 0.6 ml. The mixture was incubated in the water bath at 37 C for six minutes and 0.1 ml of dioxalated plasma was then added. The clotting time was recorded in minutes.

#### *Technic of Complement Titration*

Two methods of complement titration were employed, one based on the time and the other on the amount required for 50 per cent hemolysis at constant time. Similar results were obtained with both methods but only the former is described since it provides a more convenient comparison with the results of the clotting tests.

Determinations of time of hemolysis were made in a total volume of 2.0 ml in the calibrated tubes of a Coleman Junior spectrophotometer at wave length 580  $\mu$ . The T per cent transmission reading corresponding to 50 per cent hemolysis was determined by measurement of color standards prepared from known proportions of hemolyzed and unhemolyzed cells and an amount of inactivated complement similar to that used in the tests. The readings were made with the cells in suspension. In the preliminary titration, complement was used in amounts of 0.4, 0.2, 0.15, and 0.1 ml of a 1:25 dilution. Volumes were equalized with physiologic salt solution to 1.6 ml before the addition of 0.4 ml of sensitized sheep cells. Incubation was at 37 C in the water bath and the time required for 50 per cent hemolysis was recorded. An amount of complement which required twelve minutes for 50 per cent hemolysis was used in the following experiments. The different amounts of inactivated serum, disodium phosphate, and magnesium chloride were added to this unit quantity of complement, the volumes made up to 1.6 ml with physiologic salt solution, and 0.4 ml of sensitized cells added. Readings were made at frequent intervals during incubation and the time required for 50 per cent hemolysis recorded.<sup>8</sup>

#### *Technic of Quantitative Titration of Syphilitic Sera by Complement Fixation*

Method I<sup>14</sup> was employed but in one set of tests physiologic salt solution containing 12 micrograms of magnesium per ml for diluting antigen, amboceptor, and complement, and for equalizing volumes in different tubes of titrations were used.

### RESULTS

*The effect of magnesium chloride on the inhibition of prothrombin activation by inactivated human serum and by disodium phosphate.* Figure 1, curve 1 shows the effect of magnesium chloride on the prothrombin activation of complement. The clotting

time was reduced from ten to two minutes by the addition of 0.1 ml of a  $M/800$  solution of magnesium chloride. Curve 2 shows the effect of magnesium chloride in the presence of an inhibiting dose of inactivated human serum which without magnesium chloride gave a clotting time of fourteen minutes. The inhibitory effect was neutralized by magnesium chloride, maximum activation resulting with 0.18 ml in three minutes. Curves 3 and 4 show the effect of magnesium chloride on inhibition by disodium phosphate. One-tenth of a milliliter of a  $M/100$  solution of the phosphate showed a clotting time of fourteen minutes. This was reduced progressively with increasing quantities of magnesium chloride to two minutes. With double the amount of disodium phosphate, prothrombin activation of one hemolytic unit of complement was completely inhibited but twice the amount of added magnesium chloride completely neutralized the effect of this dose. These results suggested an equivalent relationship in the effect of these two salts.

FIG. 1—Curves 1 and 2. Effect of inactivated human serum on the enhancing action of magnesium chloride in the prothrombin activation of complement.

Curves 3 and 4. The effect of disodium phosphate ( $\text{Na}_2\text{HPO}_4$ ) on the enhancing action of magnesium chloride in the prothrombin activation of complement.

*Effect of magnesium chloride on the inhibition of the hemolytic activity of complement by inactivated human serum and disodium phosphate (figures 2 and 3).* The time required for 50 per cent hemolysis in the absence of serum and magnesium chloride was 12.2 minutes. This was increased in the presence of increasing amounts of serum to 18.8 minutes with 0.2 ml. When this dose of inactivated human serum was tested with magnesium chloride in varying amounts, the inhibiting effect of the serum was neutralized by approximately 0.35 ml of a  $M/100$  solution, and 0.6 ml resulted in a further enhancement as indicated by the reduction in time for 50 per cent hemolysis to 11 minutes. Similarly, in tests with the same quantity of complement and varying quantities of  $M/20$  sodium phosphate, slight activation was observed with 0.1 ml and inhibition with larger amounts. Five tenths of a milliliter required 22.5 minutes for 50 per cent hemolysis as shown in the first part of figure 3. As shown in the second part of figure 3, when varying quantities of magnesium chloride were used with this dose of disodium phosphate, 0.25 ml of an  $M/500$  solution of magnesium chloride completely neutralized the inhibitory

effect of the phosphate and further enhancement resulted with increasing quantities up to 0.6 ml

*Effect of magnesium chloride on the titer of syphilitic sera as determined by the quantitatively standardized complement-fixation procedure (table 1)* Under the conditions

FIG. 2.—The inhibiting effect of inactivated human serum on hemolysis by complement. The effect of inactivated human serum on the enhancing action of magnesium chloride for hemolysis by complement.

FIG. 3.—The inhibiting effect of disodium phosphate on hemolysis by complement. The effect of disodium phosphate on the enhancing action of magnesium chloride for hemolysis by complement.

employed in the test a linear relationship is observed between the amount of complement required for 50 per cent hemolysis and the amount of serum tested, the total change in complement activity or total fixation of complement is determined by linear extrapolation. The unit value as determined by titration of complement alone does not represent the unit value under the conditions of the

test, i e., in the presence of serum and antigen. The cardiolipin antigen used in these tests has, in itself, little or no effect upon complement. The serum of the test, however, has a variable effect. Therefore the titer is taken as the ratio of the total change to the change resulting from incubation with serum alone. In table 1 it may be seen that the total reaction of serum plus antigen observed with 6 different sera in tests with and without magnesium, varied markedly but the titers when expressed as the ratio  $\frac{\text{serum} + \text{antigen}}{\text{serum alone}}$  were essentially the same.

TABLE 1—The Effect of  $Mg^{++}$  Treated Complement in the Quantitative Complement Fixation Test for Syphilis

### DISCUSSION

The results confirm those of previous investigators<sup>2</sup> in showing the enhancement of the hemolytic effect of complement by magnesium. They demonstrate also a parallel effect of magnesium on the coagulative activity of serum. In both cases the influence of magnesium is inhibited by serum and by disodium phosphate. It has been suggested<sup>2</sup> that the greater effect of magnesium ions over calcium or other cations on the hemolytic activity of complement, implies its greater importance in this phenomenon. Indeed the explanation has been offered that calcium may act by displacement of magnesium from a complex. It should be borne in mind that the opposite may also be true, namely, that the enhancing effect of magnesium ions is due to a sparing of calcium ions from the serum phosphates. The fact that the addition of ionized calcium salts to complement does not increase significantly its hemolytic activity appears to render this explanation unlikely, but it is indeterminate whether or not the addition of amounts of  $Ca^{++}$  equivalent to those that might be liberated as a result of the sparing action of  $Mg^{++}$  would increase the calcium ion concentration of serum. On the other hand, the idea of a sparing effect on calcium seems logical in relation to the clotting phenomenon, in which ionized magnesium salts appear to be inactive in the absence of calcium. The parallel behavior of magnesium in enhancing the clotting and complement activities of serum, and parallel behavior of disodium phosphate and of serum in antagonizing this effect suggest a common cause, whatever it may prove to be.

The use of magnesium chloride may introduce error into complement fixation tests when the effect on the reaction of syphilitic serum and antigen is not considered in relation to the effect on the reaction of serum alone.

## SUMMARY

Magnesium chloride enhances the coagulation and complement activities of blood serum in parallel degree. These enhancing effects are inhibited by inactivated serum or by disodium phosphate.

Distortion in the results of complement-fixation tests occurs with the addition of ionized magnesium salts to the system. This is due to the antagonistic effect of the inactivated test serum. In the quantitatively standardized test, however, where the titer is expressed as the ratio of the reaction of serum and antigen to that of serum alone, the findings are the same with or without added magnesium salts.

## THE ABSENCE OF THE HETEROPHILE REACTION IN THE SPINAL FLUID IN INFECTIOUS MONONUCLEOSIS

By COMMANDER HAROLD A. LYONS (MC) USN, AND LT (JG) J. GRANT HARRISON  
(MC) USN

THE DEMONSTRATION in 1932 by Paul and Bunnell<sup>1</sup> that the blood serum of patients with the sporadic form of infectious mononucleosis contained antibodies against sheep erythrocytes in concentrations far above a normal titer was an important advance in the study and diagnosis of this disease. It gave a good test for the recognition of the individual case, allowed the linking of the sporadic and the epidemic forms of the disease<sup>2</sup> and permitted the establishment of certain epidemic fevers as infectious mononucleosis.<sup>3</sup> The test has been reported to be positive in 92 per cent of the sporadic cases,<sup>4</sup> and is consistently negative when performed in many diseases.<sup>5-7</sup> Recently, Gutner and Fisher<sup>8</sup> have described a case of chronic melioidosis with a persistently high heterophile titer (None of the differential absorption tests described below were done.) Even in those cases in which horse serum was previously administered, the reaction can be differentiated from infectious mononucleosis by the appropriate methods.<sup>9, 10</sup> Conditions producing Forssman type antibodies (such as *E. coli* bacteremia, the use of parenteral liver extract, etc.) can be distinguished by the fact that the antibodies are not absorbed by ox cells.<sup>11-13</sup> In infectious mononucleosis, the antibodies are absorbed by ox cells but not by guinea pig kidney, whereas, in normal serum the antibodies are absorbed by guinea pig kidney but not by ox cells. These differential absorption tests distinguish the various types of heterophile antibodies.<sup>10, 14</sup>

Formerly, it was thought that the antibodies of infectious mononucleosis were of the Forssman type, but now, it is definitely known that they are not. The differential absorption tests described above distinguish the heterophile antibodies occurring in various conditions from those of infectious mononucleosis. Warren<sup>14</sup> believes that the two types are interrelated, but this view is not widely held.

The spinal fluid has on occasion shown abnormalities. The pressure may be moderately elevated. Cell count increase is variable, ranging from twenty-five to three hundred cells. Lymphocytes usually predominate.<sup>15, 16, 22</sup> This is not at all uncommon, as was found in our cases. The spinal fluid sugar, and the chloride content are usually normal. The protein, however, may be increased and the Pandy Test strongly positive. Usually, the increase in the protein is out of proportion to the cell count.

It is interesting to note that although spinal fluid abnormalities have been studied in infectious mononucleosis,<sup>17-20</sup> little attention has been directed as to whether or not the heterophile antibody is present. Slade<sup>21</sup> and Landes, Reich and Perlow,<sup>22</sup> respectively, found a negative spinal heterophile in one case. Ab-

normal spinal fluid findings of pleocytosis and increased protein, however, were present

We have examined the spinal fluids in 20 cases with positive heterophile agglutinations in the serum. These findings are summarized in table 1.

The spinal fluid abnormalities that occur are similar to those reported in the literature by Thelander and Shaw<sup>23</sup> and Shafer and Weir,<sup>24</sup> with pleocytosis and

increased protein as the outstanding features. The cases described in this paper were free of any central nervous system manifestations. As will be seen from the table, there is no correlation between the serum heterophile agglutination titer and the other spinal fluid changes. Each case revealed an absence of heterophile agglutinins in the spinal fluid.

Landes<sup>1</sup> commented on the lack of reports of spinal fluid examinations for heterophile agglutinins. As noted above, he and Slade demonstrated a lack of

heterophile agglutinins in the presence of other abnormalities. This finding has been confirmed in the 20 cases in the table, and if their 2 cases are included, it is true for twenty-two cases.

Each case had a diagnostic titer of heterophile agglutinins in the blood serum, although agglutinins were lacking in the spinal fluid, even when other abnormalities were present. Even in the presence of spinal fluid abnormalities, clinical evidence of central nervous system symptoms or signs were lacking, but this certainly does not preclude central nervous system involvement by the disease. The converse also is true of infectious mononucleosis with cerebral signs and symptoms. Such cases may yield normal spinal fluid studies<sup>27</sup> or may parallel the neurologic involvement.<sup>28</sup>

The central nervous symptoms that occur are identified by various authors<sup>16-17, 19-24</sup> as meningitis, serous meningitis, lymphocytic meningitis, metastatic encephalomyelitis, encephaloneuritis, encephalomyelitis, neuronitis, and Guillain Barré syndrome. These various designations merely indicate the varied ways that the central nervous system is involved in infectious mononucleosis. Berce<sup>24</sup> has demonstrated with electroencephalograms that encephalitic foci are present with or without demonstrable cerebral symptoms.

The abnormal spinal fluid findings may thus be associated with various types of involvement of the nervous system, or with none. Whatever the heterophile antibody is in infectious mononucleosis, it does not appear to pass from the blood serum into the cerebrospinal fluid. Likewise, whatever the mechanism is in infectious mononucleosis that produces the not infrequently positive Wassermann reaction in the serum, it does not affect the spinal fluid, for in all the studies this reaction has been consistently negative.<sup>25, 27</sup> In what manner the other abnormal spinal fluid changes are brought about is not known. They may be due to the virus which is the probable etiologic agent of the disease or to a possible allergic reaction.<sup>28</sup> The abnormal number of lymphocytes in the spinal fluid may simply be a reflection on blood lymphocytosis, or the lymphocytes may be squeezed out from the perivascular spaces.

Jervis,<sup>29</sup> in keeping with the allergic concept, produced an acute disseminated encephalomyelitis by injection of Forssman antibodies into the carotid arteries of guinea pigs. He believed the Forssman antibody passed through an impaired blood brain barrier. However, in the experiments of Jervis, the guinea pig tissue, including the brain, probably contains Forssman antigen with which the injected antibody might well react. Human tissues do not contain Forssman antigen.

Recent electrophoretic studies of the serum proteins throw some light on the subject of antigen-antibody reaction, but have not as yet been extensively studied in the spinal fluid.<sup>30, 31</sup> It has been shown that the beta and gamma globulin serum proteins are elevated, and that the heterophile reaction, like all antibody reactions, is due to this elevation.

Because of the protein manifestations of infectious mononucleosis, and the delayed development of the heterophile reaction or the lack of its presence in the serum, abnormal spinal fluid findings might be misleading. The fact that a heterophile antibody does not occur in the spinal fluid reveals that this cannot aid in the diagnosis.

## SUMMARY

The spinal fluid was studied in twenty cases of infectious mononucleosis proved by clinical picture, blood studies and serological examination. It may be concluded that in acute cases of infectious mononucleosis, the heterophile antibody does not pass into the spinal fluid, but that there may be an increase in cell count, particularly lymphocytes, and in protein content, which is not necessarily proportional to the cell count elevation. These findings have no correlation with central nervous system signs or symptoms.

# A FACTOR IN SERUM WHICH ACCELERATES THE CONVERSION OF PROTHROMBIN TO THROMBIN

## II ITS EVOLUTION WITH SPECIAL REFERENCE TO THE INFLUENCE OF CONDITIONS WHICH AFFECT BLOOD COAGULATION

By BENJAMIN ALEXANDER, M D , ANDRE DE VRIES, M D ,\* AND  
ROBERT GOLDSTEIN, M D

*With the technical assistance of EUNICE ADDELSON and ELAINE PROMISEL*

IN A PREVIOUS communication,<sup>1</sup> a serum factor was described which accelerates the conversion of plasma prothrombin to thrombin by thromboplastin plus calcium, and a method for its determination was reported. This agent, labelled serum prothrombin conversion accelerator (SPCA), is distinct from thrombin, thromboplastin and labile factor. Insufficient data are available to establish the identity or nonidentity of this factor with serum Ac globulin of Ware et al.<sup>2</sup> or Factor VI of Owren,<sup>3</sup> substances with similar physiologic properties.

This paper presents data concerning the evolution of SPCA in human subjects under certain conditions which affect blood coagulation. Similar observations in various hemorrhagic disorders are reported elsewhere in this issue.<sup>4</sup>

### METHOD

SPCA was determined by a method based upon the effect of the admixture of serum on the prothrombin time of normal plasma.<sup>1</sup> The activity of SPCA is expressed as the enhancement, in per cent, of the prothrombin activity of a serum plasma mixture over and above the algebraic sum of the prothrombin activities of each component. Coagulation time of whole blood was determined by a modification of the Lee and White method.<sup>5</sup>

### RESULTS

*Evolution of SPCA following Coagulation* In previous studies, SPCA was demonstrated in serum obtained from normal blood 1 hour after coagulation.<sup>1</sup> The amount of SPCA which evolves at various intervals after clotting is shown in table 1. Immediately after coagulation, SPCA is low, whereas, as has also been shown by other investigators,<sup>6</sup> serum prothrombin is high. Within 15 minutes, SPCA increases concomitant with a decrease in serum prothrombin activity. During the next 45 minutes, some prothrombin activity tends to reappear in the serum, and SPCA activity tends to decrease somewhat.

*Normal Variation in SPCA and Serum Prothrombin* The SPCA in 95 normal subjects one hour after blood coagulation varied between 43 and 271 (fig. 1) with a mean of 99.4. The prothrombin activities of the same sera ranged between 0 and 32 per cent.

tivity of the plasmas and their respective sera. Nor was there any apparent relation between the clotting time in glass and SPCA or serum prothrombin activity.

*Effect of Accelerating Coagulation.* It is well known that agitating freshly drawn blood accelerates coagulation. This procedure also accelerates SPCA evolution, increases the amount of it evolved and decreases residual serum prothrombin

activity (table 2) Defibrination of freshly drawn blood by vigorous shaking yields serum which is very rich in SPCA and practically free of prothrombin activity. The addition of rabbit brain thromboplastin extracts (prepared as for prothrombin determinations from Difco thromboplastin) to blood also accelerates its

coagulation, increases in most instances the amount of SPCA\* and at the same time renders the serum practically devoid of prothrombin activity (table 3) The question whether this effect of thromboplastin supplements is intimately related to

\* Strangely enough the addition of rabbit brain thromboplastin to freshly drawn dog blood results in decreased SPCA in contrast to the effect on human blood

actual clotting was studied by adding thromboplastin to serum. The addition of thromboplastin to *nonoxalated* serum increases the amount of SPCA activity in contrast to what obtains with *oxalated* serum. The serum prothrombin activity was unaffected in 1 experiment and decreased slightly in another, but was always demonstrable whereas the serum from blood clotted with thromboplastin supplements was always devoid of prothrombin activity.

SPCA has been shown to be distinct from thromboplastin.<sup>1</sup> Nevertheless it is conceivable, in view of evidence that thromboplastin is not consumed during coagulation,<sup>7</sup> that the enhancement in SPCA induced by additions of thromboplastin might be related to unconsumed thromboplastin remaining in the serum. Experiments, designed to explore this possibility, revealed that thromboplastin, added to oxalated serum, in proportions comparable to those added to blood not only failed to increase the SPCA activity but in some instances decreased it.\*

\* Serum withdrawn and oxalated 1 hour after coagulation.

† Serum withdrawn and oxalated immediately after coagulation.

*Effect of Retarding Coagulation.* Prothrombin activity and SPCA were measured in the serum from blood drawn and allowed to clot in siliconized apparatus according to the technic of Jacques et al.<sup>8</sup> Parallel with retardation of coagulation the serum showed abnormally high prothrombin activity and small amounts of SPCA.

The effect of heparin was also investigated. A fixed volume of venous blood was added to increasing concentrations of the anticoagulant (table 4). Although coagulation was retarded substantially in the first two samples, SPCA and prothrombin activity of their sera were unaffected. At larger concentrations of heparin SPCA was markedly reduced and residual prothrombin activity was abnormally high. It appears that the smaller concentrations of heparin increased antithrombin activity without affecting the speed or the amount of prothrombin conversion to thrombin. With larger amounts, this phase of coagulation was also disturbed.

To prove that the above observations were not attributable to heparin carried over into the serum, experiments were performed in which the anticoagulant was added to plasma mixtures in concentrations which would obtain if the serum contained all of the heparin unaltered. The anticoagulant failed to affect substantially the prothrombin activity of the plasma mixtures even in those concentrations

\* Thromboplastin added to oxalated dog serum always decreased its SPCA activity.

which retarded coagulation of fresh blood markedly \* It is accordingly evident that the above observations are not artifacts referable to the mere presence of heparin in the serum-plasma mixtures upon which prothrombin activities were determined

*Clot Accelerating Effect of Serum* 2.0 cc of blood from a normal subject were added to 0.1 cc of oxalated serum prepared in the usual manner but subjected to incubation (37 C) for two hours in order to assure maximal inactivation of thrombin Its SPCA activity was 173 The clotting time of the normal blood-serum mixture was 3½ minutes contrasted with a clotting time of the blood alone of 12 minutes This clot accelerating effect was not due to thrombin since the same serum added to oxalated normal plasma (1 part serum to 10 parts plasma) failed to induce clotting in 3 hours whereas approximately 5 units of thrombin to 1.0 cc of plasma clotted the mixture immediately It is noteworthy that the serum obtained from the whole

TABLE 4.—*SPCA Evolution and Residual Serum Prothrombin Activity in Heparinized Blood*

Hep added	Cl T	SPCA activity	Serum proth activity
units per 2 cc blood	min	per cent	
0	3	59	14
0.16	12	63	3.3

1.25	39	8	90.0
1.66	54	13	80

\* The plasma prothrombin activity of this blood was 90 per cent of normal.

blood-serum mixture whose clotting was accelerated did not show greater SPCA than the serum from the blood allowed to clot alone

*SPCA in Subjects Receiving Dicumarol* It was of interest to investigate the relation between the amount of prothrombin available for conversion to thrombin and the evolution of SPCA The concentration of this factor was followed in a subject who received dicumarol for treatment of myocardial infarction † The administration and withdrawal of the drug affected plasma prothrombin concentration and SPCA activity in the same direction (fig 3) Similar results were obtained in a normal dog which received dicumarol parenterally

Hypoprothrombinemic blood from 26 subjects with myocardial infarction who received dicumarol for treatment‡ was studied Their plasma prothrombin concentrations were between 3.8 and 10 per cent of normal (mean 7.1) The SPCA's ranged between 8.4 and 43 (mean 25, S D 9.7) The serum prothrombin activities were usually less than that of normal serum, never exceeding 4 per cent

\* It appears that the antithrombic action of heparin in these concentrations does not influence the prothrombin times markedly

† This patient showed no additional manifestation of phlebothrombosis or thromboembolism

‡ Part of a study supported by the U S P H on the effect of dicumarol on the thrombotic complications of myocardial infarction

In view of the observations that thromboplastin added to freshly drawn blood resulted in much greater SPCA, similar experiments were done on hypoprothrombinemic blood from 8 subjects. SPCA was increased substantially in only two instances, although clotting was accelerated not only in these cases but also in those where SPCA was unchanged.

FIG 3

### DISCUSSION

The ranges of both serum prothrombin conversion accelerator and residual prothrombin activity in serum removed and oxalated one hour after coagulation have been delineated. The explanation for the wide variations is obscure. Two factors just be considered in SPCA evolution (1) speed of prothrombin conversion to thrombin and (2) the absolute amount of prothrombin converted. From the results obtained with mechanical agitation of, and with thromboplastin supplements to, clotting blood, it is evident that accelerating coagulation increases the amount of SPCA formed. Inhibition of clotting by large amounts of heparin or by siliconized apparatus suppresses SPCA evolution.

It should be pointed out that concomitant with accelerating coagulation more prothrombin is converted to thrombin as evidenced by less prothrombin activity remaining in the serum. Conversely more serum prothrombin is found when coagulation is retarded by silicone or large amounts of heparin. Whether under these conditions the substantial residual serum prothrombin is intimately related to the decreased SPCA or whether it, too, is simply a reflection of the retarded coagulation

requires elucidation. It would appear from experiments on dicumarolized blood that the total amount of prothrombin converted to thrombin plays an important role in the total amount of SPCA which can be evolved. This is predicated upon the assumption that dicumarol does not decrease, simultaneously with plasma prothrombin, a precursor of SPCA. The validity of this assumption, however, has yet to be substantiated.<sup>9</sup>

It is known that the coagulation of dicumarolized blood is prolonged under certain conditions.<sup>10, 11</sup> That this degree of retardation per se cannot, however, explain the low SPCA of serum from dicumarolized subjects is indicated by the inability, in most instances, of increasing SPCA development by accelerating coagulation of dicumarolized blood with thromboplastin.

It therefore appears that the amount of prothrombin converted to thrombin is one of the factors determining the amount of SPCA evolved. Another determinant is the velocity of prothrombin conversion. Both depend, *inter alia*, upon the concentrations of prothrombin and thromboplastin. That no correlation was evident between SPCA and the plasma-serum prothrombin activity difference in normal subjects may be referable to variation from individual to individual in the rate with which thromboplastin evolves after blood is shed.

An increment in SPCA, similar to that induced by thromboplastin added to freshly drawn normal blood, can also be produced by adding thromboplastin to serum which contains small amounts of prothrombin activity. That this enhancing effect is not obtainable if the serum is oxalated prior to the addition of the thromboplastin suggests that calcium is required for SPCA formation. It is striking that substantial increments in SPCA are thus obtained although only slight amounts of additional prothrombin are apparently consumed.

The *in vitro* action of heparin is of particular interest. Moderate amounts of the anticoagulant retard coagulation without, however, affecting either the amount of SPCA evolved or the amount of prothrombin which is consumed during coagulation. If anything, prothrombin consumption is increased, probably as a result of the greater interval provided by the retarded coagulation for the reaction to proceed. Although the anticoagulant is said to have antiprothrombic<sup>12</sup> as well as antithrombic<sup>13</sup> properties, moderate doses seem to act by enhancing the latter. Larger doses retard coagulation also by inhibiting the evolution of thromboplastin from platelets or by otherwise preventing the conversion of prothrombin to thrombin. Concomitant with this, SPCA evolution falls off.

Of fundamental importance is the ability of serum to accelerate the coagulation of whole blood. Its practical significance derives from the realization that this may be the mechanism underlying clot propagation *in vivo*.

Thrombin has been excluded as the clot promoting agent in serum. Since, however, it has been shown that thromboplastin is not consumed in the process of blood coagulation, it is possible that the clot accelerating action of serum is due to unconsumed thromboplastin liberated during blood coagulation. That thromboplastin can thus be implicated is highly unlikely since serum has only slight effect on the clotting time of hemophilic blood, which is very sensitive to thromboplastin.<sup>14</sup>

The value of dicumarol in the prevention and treatment of thromboembolism may well be related to its interference with SPCA evolution

### SUMMARY

- 1 The evolution of a factor in serum which accelerates prothrombin conversion to thrombin has been studied in normal subjects
- 2 Mechanical agitation of fresh blood or the addition of thromboplastin supplements increases the amount of SPCA evolved and decreases the amount of prothrombin activity remaining in the serum
- 3 Retarding coagulation by large doses of heparin or by handling the blood with siliconized apparatus decreases SPCA evolution and increases residual serum prothrombin activity
- 4 Hypoprothrombinemic blood resulting from dicumarol administration evolves subnormal amounts of SPCA during its coagulation

# A FACTOR IN SERUM WHICH ACCELERATES THE CONVERSION OF PROTHROMBIN TO THROMBIN

## III ITS RELATIONSHIP TO THE COAGULATION DEFECT OF THROMBOCYTOPENIC BLOOD

By BENJAMIN ALEXANDER, M D , AND ANDRE DE VRIES, M D \*

*With the technical assistance of EUNICE ADDELSON*

THE EXACT role of the platelet in blood coagulation is the subject of considerable controversy. Although thrombocytopenic plasma exhibits retarded coagulation, a prolonged clotting time is rare in thrombocytopenic purpura.<sup>1-3</sup> This has been explained by the theory that even in severe thrombocytopenia sufficient thromboplastin is elaborated to produce normal coagulation.<sup>4</sup> In any event, the hemorrhagic manifestations of thrombocytopenic purpura have generally been ascribed either to a great reduction in blood platelets, to capillary dysfunction<sup>5</sup> or to inadequate clot retraction rather than to abnormalities in coagulation itself. It is the purpose of this paper to present observations which indicate that the coagulation of thrombocytopenic blood is profoundly disturbed.

In a previous communication<sup>6,7</sup> an agent was described in serum which accelerates the conversion of prothrombin to thrombin in the presence of thromboplastin plus calcium. While insufficient data are available to establish the identity or non-identity of this substance with other factors reported to have similar attributes,<sup>8,9</sup> some of its biochemical and physiologic properties have been described, a method for its determination given, and its elaboration in the coagulation of normal blood delineated.

### METHODS

The agent, serum prothrombin conversion accelerator (SPCA), is measured by the enhancement in per cent of the prothrombin activity of normal oxalated plasma induced by the admixture to it of serum obtained from the blood in question one hour after coagulation.<sup>6</sup> Before the test, the serum is oxalated and incubated for one half hour in order to inactivate thrombin.

The prothrombin activities of plasma and serum were determined by modifications of the one stage procedure<sup>6</sup>; coagulation time was measured by a modification of the Lee and White technic.<sup>10</sup> Platelets were enumerated by the method of Rees and Ecker,<sup>11</sup> and bleeding time was determined by the Duke method.<sup>12</sup>

### RESULTS

Ten subjects† with thrombocytopenic purpura were studied (table 1). All had platelet counts below 100,000 per mm.<sup>3</sup> The mean SPCA activity was 33 per cent in contrast to 99 for 95 normal subjects previously reported (7). The residual serum

prothrombin activity averaged 50 per cent\* compared with 6 per cent for normal individuals. The algebraic differences between plasma and serum prothrombin activities averaged 37.5, whereas in normals they average 90+.

Splenic artery blood obtained during the operation

procedure, there was practically no change in the SPCA. Residual serum prothrombin did, however, decrease somewhat, but as the patient relapsed about one month after operation, it again increased.

#### DISCUSSION

Evolution of SPCA during coagulation is enhanced by supplements of thromboplastin to, or by mechanical agitation of, clotting blood.<sup>7</sup> Conversely, it is markedly reduced by inhibiting coagulation by exposing blood to siliconized surfaces, a condition which interferes with thromboplastin elaboration. Concomitantly, residual serum prothrombin activity is greatly increased.

The similar observations in thrombocytopenia indicate that a decreased number of platelets is associated with insufficient evolution of thromboplastin. This results in abnormally small prothrombin conversion to thrombin associated with inadequate SPCA evolution, as a consequence of which the conversion of additional prothrombin to thrombin is retarded. That the clotting times were essentially

normal despite the clotting defect reflects the lack of sensitivity of this test. Similarly in dicumarolized plasma the coagulation time is, more often than not, normal while SPCA is small.<sup>7</sup> And in hemophilia<sup>12</sup> comparable abnormalities in residual prothrombin activity and SPCA elaboration are observed even when the clotting time is restored toward normal by the addition of normal plasma or thromboplastin extracts. These observations are understandable when it is realized that in the coagulation of blood only a very small fraction of the total plasma prothrombin need be converted to thrombin to give a normal clotting time.<sup>14</sup>

From the experiments on one subject before and after splenectomy it appears that restoration of the platelet count to normal did little to remedy the clotting defect. What relation this had to the prompt relapse of the thrombocytopenia with clinical manifestations of bleeding is obscure and demands further exploration. It seems that although the patient had a normal number of circulating platelets following operation, they may not have been qualitatively satisfactory for rectifying the defect in coagulation. This is substantiated by the fact that the addition of normal plasma or platelets therefrom to the blood of this same subject corrected the abnormality. Such a concept is in accord with interpretations by Aggeler et al. of evidence regarding variability in the functional capacity of platelets.<sup>15</sup>

The significance of these abnormalities in the pathogenesis of the hemorrhagic phenomena of thrombocytopenic purpura requires further investigation. According to Allen et al.<sup>16</sup> a circulating heparin-like anticoagulant may be present in idiopathic thrombocytopenic purpura. The clotting defect observed by us in this disease cannot be attributed to heparin since we found<sup>7</sup> that the addition of moderate amounts of heparin to freshly drawn normal blood so as to retard coagulation substantially failed to inhibit SPCA evolution or prothrombin conversion to thrombin.

### SUMMARY

The sera from thrombocytopenic blood show abnormally large residual prothrombin activity and small amounts of prothrombin conversion accelerator. The addition of normal platelets or thromboplastin corrects these abnormalities. In one subject the clotting defect persisted despite temporary remission of the thrombocytopenia consequent to splenectomy.

## STUDIES ON HEMOPHILIA

### V THE COAGULATION DEFECT IN HEMOPHILIA WITH PARTICULAR REFERENCE TO THE CONVERSION OF PROTHROMBIN TO THROMBIN AND THE EVOLUTION OF THE PROTHROMBIN CONVERSION ACCELERATOR

BENJAMIN ALEXANDER, M D , AND ANDRE DE VRIES, M D \*

*With the technical assistance of EUNICE ADDELSON*

MOST investigators agree that the conversion of prothrombin to thrombin is retarded in the coagulation of hemophilic blood. This is reflected in the high prothrombin activity of hemophilic serum.<sup>1, 2</sup> The clotting of hemophilic blood can be accelerated by the addition of thromboplastin, normal plasma, or fractions thereof. Brinkhous<sup>1</sup> and Quick<sup>2</sup> reported that such additions simultaneously increase prothrombin consumption. The latter author used this effect as a basis for assay of the antihemophilic activity of normal plasma.

Recently, substances have been described which, arising in blood during its coagulation, accelerate the conversion of prothrombin to thrombin in the presence of thromboplastin plus calcium.<sup>3, 4</sup> Their evolution and physiologic properties help explain the autocatalytic process underlying thrombin formation. In a previous publication<sup>5</sup> and elsewhere in this issue<sup>6, 7</sup> we have reported on serum prothrombin conversion accelerator (SPCA), delineating its evolution under various conditions in normal subjects and in patients with thrombocytopenic purpura. This report, concerning similar studies in hemophilia, presents data indicating that in the elaboration of this clotting factor, also, the coagulation of hemophilic blood is abnormal.

#### METHODS

Plasma and serum prothrombin activities and SPCA were determined by methods previously described.<sup>8</sup> In normal subjects<sup>8</sup> serum prothrombin activity ranges between 0-32 (mean 6.4), SPCA ranges between 43-271 (mean 99). In some experiments prothrombin was simultaneously measured by the modified two stage method of Jaques<sup>9</sup> using Parke Davis Topical Thrombin as our standard.

Clotting time was determined by a modification of the Lee and White method.<sup>10</sup> In our experience the value in 90 normal individuals was between 4 and 12 minutes (mean 7.7 S.D., 1.72).

#### RESULTS

*Serum Prothrombin Activity and SPCA in Hemophilia* The prothrombin activities of sera removed and oxalated one hour after coagulation from hemophilic blood are abnormally high. This is in accord with the observation of others.<sup>1</sup> Conversely, the SPCA activities are abnormally low (table 1). No correlation was evident between the coagulation time and these serum entities.

From the Medical Research Laboratory, Beth Israel Hospital and the Department of Medicine, Harvard Medical School, Boston, Mass.

This study supported by a grant from the Commonwealth Fund.

† The amounts of normal plasma added were contained in a volume of 0.1 cc. of a saline solution

of small amounts of thromboplastin fails to lower residual serum prothrombin activity appreciably, SPCA concentration is also unaffected. When, however, larger amounts of thromboplastin are supplied, both prothrombin consumption and SPCA evolution may be greatly increased, attaining normal values (table 2). It is striking, however, that in two subjects substantial amounts of serum prothrombin activity were still demonstrable although the parent blood had clotted in 180

seconds or less This is in marked contrast to what was observed in normal subjects \*

Restoration of the clotting time of hemophilic blood toward normal by the *in vitro* or *in vivo* addition of normal plasma decreases residual serum prothrombin activity substantially in some cases but it rarely reaches normal values (table 3)

TABLE 4.—*Residual Serum Prothrombin Activity in Hemophilia as Determined by the One Stage and Two Stage Procedures Subject R. R.*

0.001 serum	49
0.01 serum	33
0.001 plasma	33
0.01 plasma	21

SPCA, however, rises only slightly, even when as much as 700 cc of normal plasma are infused It is noteworthy that in other individuals coagulation may thus be accelerated without any demonstrable change in residual serum prothrombin activity (J. G., table 3) Also, even when serum prothrombin activity is decreased by the addition of normal plasma (R. R., table 3), the change is far less marked than the decrease in the clotting time

*Effect of Normal Serum on Coagulation of Hemophilic Blood* The addition of normal serum, containing substantial SPCA activity, to hemophilic blood (table 5)

accelerated coagulation only slightly as compared with the clot promoting effect of the parent plasma

*Residual Serum Prothrombin Activity in Hemophilia as Determined by the One and the Two Stage Technics* Hemophilic plasma, and sera obtained one hour after coagulation were subjected to simultaneous prothrombin determination by both the one stage and the two stage technics. Whereas by the one stage procedure serum prothrombin activity was no less (and occasionally was even more) than that of its parent plasma, by the two stage method serum prothrombin activity was markedly less (table 4)

#### DISCUSSION

That hemophilic sera contain large amounts of prothrombin has been repeatedly observed.<sup>1, 2</sup> The abnormally small evolution of serum prothrombin conversion accelerator during the coagulation of hemophilic blood indicates an additional coagulation defect which may play a significant role in the pathogenesis of the hemorrhagic phenomena in this disease. It is striking that in thrombocytopenic purpura, also, both high residual serum prothrombin activity and low SPCA are found.<sup>7</sup> Similarly, SPCA concentrations are decreased in the sera of blood rendered hypoprothrombinemic by the administration of dicumarol.<sup>6</sup> The possibility must be considered that subnormal SPCA elaboration is the common denominator underlying the hemorrhagic tendency of these various disorders.

The addition of small amounts of normal plasma can accelerate the coagulation of hemophilic blood without appreciably affecting the apparent prothrombin activity remaining in the serum. This clot promoting effect is not due to thrombin evolved from the small amount of prothrombin contained in the added normal plasma since *prothrombin free* plasma also shows full clot promoting activity.<sup>10</sup> It appears that the normal plasma acts by accelerating the evolution of thromboplastin.<sup>2</sup> This induces prothrombin conversion to thrombin in amounts sufficient to clot the blood in a relatively normal time. Since no more than 2 of the approximately 250 units of thrombin which can be formed in 1 cc of normal plasma are required for this purpose,<sup>11</sup> it is understandable how the coagulation time of hemophilic blood can be brought within normal limits by small additions of normal plasma, or indeed of thromboplastin, without significantly decreasing residual serum prothrombin. This point has been emphasized by Quick.<sup>2</sup>

The above facts may also explain the frequent clinical observation that hemophiliacs may continue to bleed despite relatively normal coagulation times induced by therapy with blood, plasma, or plasma fractions.

Quick has reported a method of assaying antihemophilic activity of plasma by its ability to induce substantial prothrombin consumption when added to hemophilic blood.<sup>2</sup> This method is less sensitive than the procedure of Alexander and Landwehr<sup>12</sup> which is based upon reduction in the coagulation time since clotting can be significantly accelerated by much smaller quantities of normal plasma than are required for significant alterations in prothrombin consumption.

An additional criticism of Quick's method arises from the discrepancy in serum prothrombin activity as determined by the one stage and two stage procedures.

This is of great interest and demands further investigation. Until it is satisfactorily explained, computations of prothrombin consumption from differences between plasma and serum prothrombin activity are to be interpreted with caution.

The addition of large amounts of thromboplastin to normal blood results in serum which is devoid of prothrombin activity.<sup>6</sup> That, in contrast, the sera of some hemophiliacs retain considerable prothrombin activity despite the fact that coagulation is extremely rapid consequent to the addition of thromboplastin indicates that clotting is still abnormal and suggests that deficient elaboration of thromboplastin is not the sole defect, at least in some cases, in the coagulation of hemophilic blood. The recent evidence regarding anticephalin<sup>13</sup> and an anticoagulant in the nature of an immune body<sup>14</sup> may bear on this point.\*

### CONCLUSIONS

It has been confirmed that hemophilic serum exhibits considerable prothrombin activity. The clotting time may be restored to normal by the addition of normal plasma or thromboplastin without affecting residual serum prothrombin activity significantly.

2. In contrast to normal, hemophilic serum is relatively incapable of accelerating the conversion of plasma prothrombin to thrombin in the presence of thromboplastin and calcium. This defect also persists despite acceleration of coagulation to normal by additions of normal plasma or thromboplastin.

3. Serum from hemophilic blood which clots rapidly in the presence of large supplements of thromboplastin may still retain substantial prothrombin activity, whereas under the same conditions normal serum is devoid of prothrombin activity.

4. There is a marked discrepancy between the prothrombin activity of hemophilic serum as determined by the one and the two stage procedures.

for persistent diarrhea but steadily became more feeble. The treatment was chiefly dietetic, and radiation treatment was not given. The leukocyte count remained low in October 1945 for instance 2,160 per cu mm, with lymphocytes 74 per cent, in August 1947 4,500 with lymphocytes 24 per cent. The sternal marrow was heavily infiltrated with lymphocytes. In September 1947 he died. Only partial necropsy was performed. A firm annular infiltration extending a little above and below the pylorus was found in the stomach. Its surface was somewhat ulcerated. There were numerous lymph nodes in the mesentery. The liver was not enlarged and the spleen weighed 315 Gm. Histologic examination revealed an adenocarcinoma in the pyloric region. There were histologic changes in the spleen, liver, mesenteric lymph nodes and colon consistent with lymphatic leukemia. In the liver only very slight periportal infiltrations were noted. There were no metastases in the organs examined.

*Comment* In this case a typical lymphatic leukemia with characteristic blood picture was demonstrated in 1941. The anamnestic data make it probable that the condition had already existed for a number of years. From 1941 until the patient's death in 1947 the leukemia had, in spite of very moderate radiation treatment, remained aleukemic. In the last two years, there had been gastric and intestinal symptoms and increasing cachexia, and at the necropsy an ulcerated adenocarcinoma was found in the region of the pylorus, but lymphatic infiltrations in the lymph nodes, liver, spleen and colon were present. No other organs were examined.

Though the rather protracted aleukemic phase after a definite leukemic beginning is unusual, there can hardly be any doubt that the patient had a genuine leukemia. The long duration of the leukemic symptoms makes it overwhelmingly probable that the cancer of the stomach was a disease of later origin.

Besides this case, we have had occasion to observe 2 cases of cancer of the stomach, in which the first diagnosis both clinically and hematologically was chronic lymphatic leukemia, but in which the leukemic symptoms disappeared little by little as the cancer of the stomach developed. The first of these has already been published,<sup>4</sup> and shall therefore only be briefly recapitulated here.

*P. I. P.* (Radium Center 2114/35) farmer born 1879. In 1935, there appeared a plum-sized swelling of lymph nodes in his axillae and groins, and at the same time he began to suffer from increasing fatigue. The lymph node swelling was constant for four months and he was admitted to the Radium Center. There was no enlargement of the liver or spleen but roentgen examination of the lungs showed enlarged hilar glands. (For the blood findings, see the condensed table 1.) Most of the lymphocytes were small, rich in chromatin, but with very sparse cytoplasm. A few were atypical with lobulated or bi-nucleated nuclei. There were a number of disintegrated cells. A brief series of spray x radiations were given seemingly with good effect. The man remained perfectly well until the fall of 1937 when dyspeptic symptoms began to develop. In another hospital exploratory laparotomy was performed and a large inoperable carcinoma of the stomach invading the liver was found. In January 1938, he was readmitted to the Radium Center to be treated with roentgen ray for the tumor of the stomach. It was treated locally. At that time there was no swelling of the peripheral lymph nodes and no enlargement of the spleen. He died November 1938. Necropsy showed a large carcinoma of the stomach, with invasion of the left lobe of the liver and metastases to small glands along the lesser curvature but otherwise no metastases were found. There were no other glandular swellings and the spleen was not enlarged. Histologically the tumor of the stomach was a typical adenocarcinoma. There were no signs of lymphatic leukemia in the liver, spleen or kidneys. In the bone marrow there were a few very small groups of small lymphocytes but otherwise normal erythromyelopoiesis.

*Comment* The results of some of the blood examinations are shown in Table 1, further details may be found elsewhere.<sup>4</sup> It will be seen that when the patient was admitted in 1935, the blood picture showed a marked lymphatic reaction and the

lymphocytes showed morphologic abnormalities such as are often seen in lymphatic leukemia. In the course of a few months, the total leukocyte count dropped to normal values and at the same time the proportion of lymphocytes decreased, until at the time of the patient's death, there was a marked relative and absolute lymphopenia. In this case, it is difficult to say when the tumor in the stomach began to develop. When laparotomy was performed in 1938, he had been ill for about two years, and at the time of that operation the tumor was already very large and inoperable. It is therefore quite possible that the leukemoid state and the neoplastic growth may have developed simultaneously.

The following case in many respects shows a similar development. Unfortunately there is no microscopic examination of the gastric tumor available, but it is reasonable to suppose that the patient had a non-leukemic malignant growth there.

E J (Radium Center 1330/47) electrician, born 1871. Past history without interest. For six months had pains in the epigastrium after meals, and occasional vomiting. In May 1947 referred to the Radium Center to be treated for carcinoma of the stomach. He had lost 3-4 Kg. in weight during the preceding six months. There had been no angina or fever in connection with his present illness. The patient was pale and emaciated. Numerous moderate enlargements of lymph nodes were present in the neck, axillae and groins, but no palpable enlargement of liver or spleen. In the epigastrium an irregular tumor was felt whose size was difficult to determine. There was no free acid in the stomach. Roentgen examination of the stomach showed a notched, irregular, eroded mass with a filling-defect for a distance of 8 or 9 cm. on the greater curvature. This was the size of an orange and extended into the lumen. On admission the sedimentation rate was 43 mm./hour, hemoglobin 77 per cent, red cells 3,680,000, white cells 11,600 with neutrophils 17, eosinophils 0 and mononuclears 83 per cent. Most of the mononuclears were of the small lymphocyte type with very scant cytoplasm and a nucleus rich in chromatin. But a few larger forms were also present with a monocytoïd configuration and structure, often with distinct nucleoli. A number of smudge cells were seen. Only a few typical monocytes were present. No McKinley cells. The sternal marrow was rich in cells and contained over 80 per cent of these atypical mononuclear cells. Microscopic examination of a lymph node puncture showed typical lymphatic leukemic changes. The Paul Bunnell test was negative. The patient was treated with x rays over the tumor of the stomach (rotatory irradiation) 160 kV., 9½ ma., through 0.5 mm. Cu + 1 mm. Al. half layer value 0.7, distance 50 cm., two

series each of 2,700 r. The treatment did not reduce the size of the epigastric tumor substantially, and the roentgenographs showed only moderate regression of the tumor in the stomach. The patient was controlled as an out patient but became feebler and lost weight. The leukemic blood picture disappeared. (June 2, 3,500 white cells 46 mononuclears, June 17 4,800 white cells 16 mononuclears and no atypical cells. The mononuclear cells could now easily be divided in 9 per cent typical monocytes and 7 per cent lymphocytes.) In June 1947, the sternal marrow showed almost normal conditions, with only 14 per cent lymphocytes in the smears. The swelling of the lymph nodes also gradually diminished and by August of the same year they were only of hazelnut size. During the following months the patient was readmitted for renewed treatment. The lymph nodes had become still smaller, but the tumor of the stomach had become larger. The blood counts were as follows: hemoglobin 45 per cent, red cells 2,100,000, white cells 6,400, platelets 4,000. Neutrophils 83.5, eosinophils, 0.5, lymphocytes 1.5, monocytes 6. No atypical cells. He was again given roentgen treatment this time to two fields, each of 5 x 10 cm, over the epigastrium 160 Kv 4 ma through 1 mm Cu + 1 mm Al distance 40 cm 600 r, in all to each field. During his stay he became steadily feebler and when discharged a month later he was rather cachectic. At the time of discharge there was no glandular swellings except a single bean-sized node on one side of the groin. The blood counts at this time (October 10) were: hemoglobin 62, red cells 3,230,000, white cells 5,400, neutrophils 88, lymphocytes 10, monocytes 2. As will be seen there was now both relative and absolute lymphopenia. The sternal marrow showed no evidence of leukemia. Three weeks later he died at home, and unfortunately we did not succeed in obtaining a necropsy.

*Comment.* This third case has some resemblance to the foregoing. On admission, there were clinical and hematologic signs of lymphatic leukemia with typical changes in the sternal marrow and the examined lymph node. At the same time, a tumor was found in the stomach, and as this grew larger all signs of leukosis disappeared,\* the swellings of the lymph nodes subsided, the sternal marrow became normal and at last there was marked lymphopenia in the blood. Unfortunately we were unable to examine the tumor of the stomach histologically, but it is hardly possible that it could have been a lymphatic leukemic growth, as these are extremely radiosensitive, while in this case there was very moderate regression in spite of intensive local irradiation with roentgen rays.

The coexistence of cancer and leukemia in the same individual has been observed rather often, and some of the reported cases of this association have recently been reviewed by Videback.<sup>24</sup> In the present study, it is specially the combination of cancer and *lymphatic* leukemia which is of interest. Such cases have been reported by Lannois and Regaud<sup>17</sup> (cancer of the uterine cervix), Marischler<sup>18</sup> (hypernephroma), Fuhs<sup>12</sup> (cancer of the skin), Genévrier<sup>13</sup> (pulmonary cancer), Scheufler<sup>19</sup> (cancer of the skin), Brückner<sup>5</sup> (cancer of the uterine cervix) Schreiner and Wehr<sup>20</sup> (cancer of the skin, 2 cases, pulmonary cancer, 1 case, mammary cancer, 1 case), Saupe<sup>28</sup> (cancer of the stomach), Denoyer<sup>9</sup> (cancer of the larynx), Pulvertaft<sup>24</sup> (cancer of the skin), Penzold<sup>22</sup> (cancer of the stomach), Askanazy<sup>1</sup> (cancer of the esophagus), Dustin<sup>10</sup> (cancer of the stomach), Engelbreth Holm<sup>11</sup> (cancer of the lip, 1 case, cancer of the skin, 5 cases, cancer of the penis, 1 case), Hertz<sup>15</sup> (cancer of the kidney), Švejška<sup>33</sup> (cancer of the stomach, 1 case, cancer of the larynx, 1 case) Gertler<sup>14</sup> (cancer of the skin), Ovnbyl and Therkildsen<sup>21</sup> (cancer of the breast and the prostate in the same individual), Delcourt (mammary cancer,<sup>7</sup> cancer of the bile ducts in the liver<sup>6</sup>), Morrison<sup>19</sup> (cancer of the pancreas), Berk and Movitt<sup>3</sup>

\* One must consider the possible effect on the leukemia of the local roentgen ray therapy directed to the stomach. *Editor*

(cancer of the larynx), Videback<sup>24</sup> (cancer of the skin) In this review, we have omitted the combination of tumors originating in the hemopoietic tissue (lymphosarcomas, reticulosarcomas, myelomas, etc.) with leukemic blood pictures

Petri<sup>25</sup> found carcinoids in the intestines of 2 patients with aleukemic lymphatic leukemia and called attention to the advisability of a close examination of the intestine of patients with leukemia, with the view of the possible presence of such tumors, which are often small and difficult to distinguish from Peyer's patches, especially if there is also leukemic infiltration in the gut

That leukemic reactions of the myeloid type may occur in connection with malignant tumors is well known, though the mechanism of their development is not quite clear Lymphatic reactions, on the other hand, are rarely seen in connection with malignant tumors (here we again omit the special tumors arising from the hemopoietic tissue) Reich<sup>26</sup> described a curious case of an adenocarcinoma of the sigmoid in a man 55 years old with 18,700 leukocytes per cu mm, 91 per cent of which were lymphocytes The sternal marrow showed marked infiltration of lymphocytes, many of which were abnormal The day before he died, the leukocyte count rose to 103,000 per cmm, with 95 per cent lymphocytes, but at necropsy there was no leukemia Reich suggests that the unusual hematologic picture may have been due to an action of the carcinoma on the hemopoietic tissue The necropsy revealed generalized metastases, including the bone marrow Müller and Wertheimann<sup>27</sup> mention a case of lymphocytosis associated with mammary cancer with metastases to spleen, lymph nodes and bone marrow There were 33,000 leukocytes per cmm, with 63 per cent lymphocytes At necropsy, no leukemic changes were found in the organs A case which is not quite clear, however, is reported from Russia, by Šal<sup>28</sup> The patient was a man, 55 years old, with 434,000 leukocytes per cu mm, 99 per cent of which were lymphocytes At necropsy, cancer of the peritoneum (? primary tumor) was found, with enlargement of the spleen and liver, but no enlargement of the lymph nodes The bone marrow was normal In the case of a woman 29 years old, reported by Winans,<sup>29</sup> blood examinations showed up to 18,500 leukocytes per cu mm with 85 per cent lymphocytes, but there was no enlargement either of the spleen or the lymph nodes Some time afterwards, she experienced pains in the lower part of the abdomen, and at the operation a pseudomucinoid cyst was removed from the right ovary, and a papillary adenoma from the left The lymphocytosis disappeared, but had already decreased before the operation and seemed to have been due to a febrile infection of the upper air passages and not to the tumors Rohr and Hegglin,<sup>30</sup> in their monograph on the occurrence of tumor cells in sternal punctures, briefly mention a case of a simple, solid carcinoma of the cardia in a man, 75 years old, with 25,000 leukocytes per cu mm, 34 per cent of which were lymphocytes Die Lymphocyten sind vorwiegend jung (Bild der lymphatischen Reaktion) In the sternal marrow, there were 17,600 per cent lymphocytes besides the tumor cells In Silberstern and Pechterewa's case<sup>31</sup> of a cancer of the rectum in a 72-year old male there were 18,000 leukocytes with 85 per cent lymphocytes, without other signs of leukemia The autopsy revealed metastases to the regional lymph nodes but no leukemic involvement of the organs and only slight lymphocytic infiltration of the liver and bone marrow

In comparison with the myeloid reactions in malignant tumors, lymphatic reactions are extremely rare. Moreover, they seem to be different from the myeloid in several respects, thus they, in contrast to these, which as a rule are a late phenomenon, often occur at a very early stage of the development of the cancer, sometimes even at the same time as the latter. The mechanism which elicits the lymphatic reactions in these cases is quite obscure. Silhol<sup>22</sup> thought that metastases from cancer of the stomach to regional lymph nodes might give rise to lymphocytosis, but the early occurrence of the lymphatic reactions makes it doubtful if metastases to lymph nodes play any part. Another strange thing about these reactions is, as far as one can conclude from a rather few cases, their tendency to become less pronounced as the malignant tumor grows larger. The same tendency can be noticed as regards the lymphatic leukemias associated with cancer, for instance, in Marischler's<sup>18</sup> case of hypernephroma combined with chronic lymphatic leukemia, and in the first of the cases reported in the present communication. In Marischler's case, the number of lymphocytes steadily decreased, and the lymph nodes gradually became smaller as the disease developed. He supposed that this was due to an effect of cancer toxins on the leukemic process, similar to the well-known effect of certain infections. It must be remembered, however, that the lymphatic tissue is apt to be strongly affected by cachexia and inanition, conditions which appear with malignant tumors, especially when these have their origin in the gastrointestinal tract.

Even in the uncomplicated cases of chronic lymphatic leukemia there is often a fall in the lymphocyte content of the blood during the last days of life, and the spleen and lymph nodes may become smaller, even without therapy, though, of course, this does not mean that there is an entire disappearance of the leukemic changes in the organs. Of course it is a question if certain malignant tumors of the gastrointestinal tract do not have a repressing effect on the leukemic processes in the organs. That tumors of the stomach do not always have this effect, is clearly seen from Penzold's case, in which the neoplastic growth and the leukemic processes existed side by side and were even believed by Penzold to have activated each other. It is clear that as basis for judgment respecting the reciprocal effect of the tumor and the leukemia only those cases can be used in which the observation time has been sufficiently long, and in which the patient died either of the leukemia or of the malignant tumor, and not of some irrelevant disease. In Dustin's case,<sup>10</sup> for instance, of stomach cancer with lymphatic leukemia, the patient was only observed a few days and died of an intercurrent infection.

#### SUMMARY

The author reports the case of a patient with chronic lymphatic leukemia, who after some years developed dyspeptic symptoms, increasing cachexia, and eventually died. The leukemia had been subleukemic for several years. Necropsy revealed an adenocarcinoma of the pylorus and lymphatic leukemic changes in the lymph nodes, spleen and liver. In two other cases a lymphatic leukemic blood picture and clinical signs of leukemia (including lymph node enlargements and leukemic changes in the bone marrow) gradually disappeared as tumors of the stomach de-

veloped, and in both cases the leukemic blood picture was replaced by a state of lymphopenia. In one of them, the necropsy revealed an adenocarcinoma of the pylorus, in the other, necropsy could not be obtained, but the clinical picture and the radiosopic examinations strongly suggested carcinoma of the stomach in this case, too. These last two cases must be interpreted as lymphatic leukemoid states produced by the presence of the carcinomatous neoplasms, though the possibility can not be excluded that certain carcinomas of the gastrointestinal tract may be capable of primarily or secondarily exercising an inhibitory influence on the leukemic processes.

In connection with the report of these cases, the author reviews the cases from the literature, of lymphatic reactions in cancer and of the coexistence of lymphatic leukemia and cancer in the same individual.

# LYMPHOCYTIC LEUKEMOID REACTION OF THE BLOOD ASSOCIATED WITH MILIARY TUBERCULOSIS

By FRANK H. GARDNER, M D , AND STACY R. METTIER, M D

BLOOD pictures similar to those of myelocytic and lymphocytic leukemia have been reported<sup>1-6</sup> to occur not infrequently in patients with miliary tuberculosis. These reports indicate that there is a marked 'shift to the left' of the leukocytes in the peripheral blood to include varying percentages of myelocytes and myeloblasts. This hemogram is associated with an absence of the characteristic leukemic infiltration of the tissues on postmortem examination.

Landon<sup>7</sup> has reported a case of tuberculous bronchopneumonia in a 16 year old girl in whom the white blood cell count rose to 36,800 per cubic millimeter of blood, 95 per cent of the cells were considered to be immature lymphocytes. Coley and Ewing<sup>8</sup> reported the case history of a 42 year old woman with diffuse tuberculosis of the lymph nodes. The white blood cell count was 8,000 cells per cubic millimeter of blood, of which 84 per cent were reported as of the mononuclear type. The mononuclear cells were considered to be lymphocytes. The structural changes in the lymph nodes showed acute necrosis without caseation and without tubercle formation.

Leibowitz<sup>9</sup> has reported the occurrence of a predominantly myeloblastic blood picture in a patient with symptoms of sepsis associated with miliary tuberculosis. Examination of tissues removed from various organs showed necrotic lesions containing myriads of tubercle bacilli but without tubercle formation.

One case with a monocytic leukemoid reaction has been studied.<sup>10</sup> The patient showed a white blood count of 82,000 cells per cubic millimeter of which 42 per cent were monocytes. Autopsy revealed generalized tuberculous adenitis. It was of interest that the monocytes were found only in association with the tuberculous foci in the lung and liver. The author suggested that the monocytic response might be due to a reactive irritation of the reticulo-endothelial system.

The following two case histories are reported as examples of a lymphocytic leukemoid response to miliary tuberculosis.

## CASE REPORTS

### CASE I\*

R. O., a 59 year old white female, entered the Mt. Zion Hospital on January 5, 1945. She complained of generalized malaise and a swelling in the left side of her neck. Four months previously the patient had noted that she tired easily and had lost 20 pounds in weight in one month's time. Profuse perspiration at night caused her considerable discomfort. She was aware of dizziness upon sudden change of position. Just prior to entry it had been observed that she was febrile.

The patient stated that a nodular mass had been removed surgically from the left side of her neck at the age of 16. This consisted of one walnut-sized node surrounded by many smaller nodules. In 1938

From the Division of Medicine, University of California Medical School, San Francisco, California.  
Aided by a grant from the Edward S. James Foundation.

\* We wish to thank Dr. Roy Morris for permission to use this case history.

at the age of 53 the patient again entered the hospital because of the appearance of a mass in the left side of the neck which extended from the mastoid process to the angle of the mandible. The mass was firm in consistency, smooth in outline, and fixed to the underlying structures. Six exposures to roentgen ray did not alter its size, and it was surgically removed. The pathologist reported atypical tuberculosis, and acid fast organisms were found in the stained sections. In January 1943 she saw her physician because serous fluid drained from the area of the wound in the left side of the neck, where the nodes had been excised. With symptomatic treatment this sinus healed in two months. Nine months later she was seen again because of climacteric symptoms. At this time the wound was healed and she had gained weight. She did not see her physician again until the present illness.

FIG. 1—CASE 1 ( $\times 1000$ ) Film prepared from peripheral blood and stained according to Wright's technic. Note the immature lymphocytes.

Physical examination revealed a well-nourished woman in no apparent distress. Blood pressure was 116/70 mm Hg, pulse 88. There was a large, matted, movable mass in the region of the left submental triangle. Small nodes were palpable bilaterally in the anterior and posterior cervical chains. The heart was not enlarged and there were no cardiac murmurs. No abnormal findings were apparent on physical examination of the chest. The tip of the spleen was palpable 4 cm. below the left midcostal margin. The rest of the physical examination was essentially negative. No other adenopathy was noted.

Urinalysis revealed 1+ albumin, specific gravity of 1.019, no sediment abnormalities on microscopic examination. Blood examination showed hemoglobin of 8.9 Gm. or 58.4 per cent (Sahli); the red blood cell count was 3.02 million per cubic millimeter of blood; the white blood cell count was 6,100 per cubic millimeter of blood. The differential count showed lymphoblasts 11 per cent, prolymphocytes 64 per cent, lymphocytes 24 per cent, granulocytes 1 per cent. Almost all of the cells showed characteristics of young lymphocytes and lymphoblasts. The cytoplasm was deeply basophilic and contained a moderate number of azure granules. The chromatin was diffuse and between its meshes could be discerned several large nucleoli (figure 1). Differential counts done on four different occasions between January 6 and January 29, 1945, showed results similar to the first count.

In addition to symptomatic treatment the patient received four blood transfusions over a period of two weeks with no subjective or objective improvement. The patient maintained a swinging daily temperature curve with peaks at 39.5 C and 40.5 C. The fever followed no specific pattern but for the most part was above 38 C. About February 4, 1945 she began to have periods of disorientation. On February 11, her respirations were labored and the patient became comatose and expired twenty nine days after entry into the hospital.

**Clinical diagnosis:** Tuberculous adenitis, acute lymphocytic leukemia, aleukemic myelophthisic anemia.

### *Necropsy*

**Gross Examination:** The body was that of an obese white woman with generalized icterus. Multiple petechiae were present over the body and about both eyes. No palpable subcutaneous lymph nodes were noted. There was no excess free fluid in any of the body cavities. The organs were normally disposed.

The heart weighed 320 grams and was of usual contour and quite flabby. It was yellow-tan, striated and soft. The coronary ostia and the major coronary branches were patent.

The weight of the left lung was 620 grams, the right 410 grams. The pleural surfaces were smooth, but on cutting were crepitant and dark red. The trachea and bronchi contained a moderate amount of frothy hemorrhagic material. The tracheobronchial lymph nodes were large, measuring up to 4 cm. They were grayish white when sectioned.

The liver weighed 1900 grams and was quite soft. The capsule was smooth and on the cut surface the parenchyma was yellow and finely dotted with red. The gallbladder, pancreas and adrenal glands showed no gross changes.

The gastrointestinal tract showed no gross changes. Near the cecum there was a mass of translucent tissue resembling matted lymph nodes which measured 6 cm. in diameter. On section this was grayish white with yellow foci.

The spleen weighed 440 grams and was soft. On the cut surface it was dark red dotted with gray.

The combined weight of the kidneys was 380 grams. On cut surfaces they showed multiple hemorrhagic markings but otherwise were not abnormal. The right ovary was replaced by a cystic mass filled with thick hemorrhagic material. Otherwise the pelvic organs were normal. There were no additional gross abnormalities of significance.

### *Microscopic Examination*

**Heart:** The myofibrillae were thin with prominent striations and nuclei. The small vessel walls showed no changes.

**Lungs:** The alveoli were collapsed in large areas and the small vessels were distended. Elsewhere the alveoli and bronchioles contained granular eosinophilic material and a few polymorphonuclear cells.

**Liver:** The architecture was distorted by atrophy and the presence of broken-down cells in the central areas. There were many oval areas of necrotic tissue with an average diameter of one third of a lobule. These areas were scattered throughout the liver and were composed of dense eosinophilic amorphous necrotic tissue in which a few ghosted nuclei were seen. There was a fine border of scattered lymphocytes about some of the nodules. Silver stain showed the usual reticulum network intact except in the caseous areas. Sections of liver stained by the Ziehl-Nielsen technique revealed numerous clumps of acid-fast bacilli. No periportal lymphocytic infiltration was seen.

**Spleen:** The lymph follicles were quite small and sharply bounded by congested red pulp. Throughout the organ were necrotic foci of the same size as those observed in the liver and of similar appearance. Acid-fast organisms were noted in these caseous nodules also.

**Lymph nodes:** Sections of the lymph nodes from the cervical, tracheo-bronchial, pre-aortic and mesenteric groups showed the same picture of numerous eosinophilic oval areas of necrosis. Again they were devoid of cells, blending peripherally with lymph node structures. These areas were devoid of reticulum by silver stain and contained myriads of acid-fast organisms.

**Bone marrow:** Spread diffusely throughout the marrow were numerous areas of necrosis which were devoid of any epithelioid reaction at their borders. The blood-formative tissue was slightly hypoplastic. Megakaryocytes were rarely seen but the plasma cells were slightly increased.

**Miscellaneous:** Sections of the adrenal gland, pancreas, parathyroid, thyroid, uterus, ovaries, kidney,

gallbladder, and urinary bladder showed no changes of significance. No changes were found in the brain or meninges.

**Anatomic Diagnosis** Generalized tuberculosis of lymph nodes - (a) miliary tuberculosis (b) hypoplasia of bone marrow hemorrhagic cyst of ovary

#### CASE 2

V. L., U130787, a 73 year old man, entered the University of California Hospital on August 19, 1946, complaining of dyspnea, orthopnea, and hemoptysis. The patient's history dated back to 1918 when he had his first episode of hemoptysis, which was treated with three weeks of bed rest. Again in 1923 he had an episode of severe hemoptysis and was told at that time that he had pulmonary tuberculosis. Otherwise the past history was noncontributory. In October, 1945, the patient had a swelling of the right ankle and lower leg and a diagnosis of phlebitis was made. In February, 1946, he saw his physician because of generalized malaise. A white blood cell count at that time revealed a leukocytosis of 66,000 cells per cubic millimeter, with 95 per cent lymphocytes. There was no hepatosplenomegaly or adenopathy noted. He was given symptomatic therapy until June 18, 1946. At that time he was given Fowler's solution, 5 drops three times daily. However, the patient stopped the medication in five days because of nausea. The drug was again started and continued for the first two weeks of July. The white blood cell count averaged about 39,000 cells per cubic millimeter with 90 per cent lymphocytes at this time. During the two months preceding hospitalization, the patient had a cough productive of blood tinged sputum. He also suffered from night sweats and fever.

On entry the patient was dyspneic and cyanotic. Blood pressure was 125 systolic and 70 diastolic. The temperature was 38.2 C, the pulse 120 per minute, the respirations 30 per minute. On physical examination no adenopathy was noted. The trachea was deviated to the right and there was marked venous distention of the neck. The chest showed atrophy of the right shoulder girdle muscles. There was limited excursion of the right chest. There was flatness of the right upper third of the chest posteriorly and anteriorly to percussion. Crepitant rales were present over the entire chest with bronchial breathing over the right apex. No cardiac enlargement was noted. On deep inspiration the liver was palpable 7 cm. below the right midcostal margin and the spleen 3 cm. below the left midcostal margin. Bilateral pedal edema was present with brownish discoloration over the right ankle.

#### Laboratory Data

The urine showed faint albuminuria and had a specific gravity of 1.026. There were no abnormal findings in the sediment. Examination of the blood revealed hemoglobin of 9.5 grams or 66 per cent (Sahli). The red blood cell count was 3.5 million per cubic millimeter, white blood cell count was 42,500 cells per cubic millimeter, the differential count showed prolymphocytes 6 per cent, lymphocytes 77 per cent, degenerative cells 13 per cent, granulocytes 4 per cent. An adequate number of platelets were present on blood films prepared with Wright's stain. The sputum contained large numbers of acid fast organisms. The electrocardiogram showed an abnormal record suggesting coronary artery disease.

The patient was immediately digitalized with 8 cc. of Cedilanid intravenously and soon obtained marked relief from dyspnea. He was then given a maintenance dose of digitalis folia, 0.1 Gm. twice daily. The cyanosis receded slowly but the patient continued to have a fever of between 38 and 39 C. at all times. A chest x-ray taken shortly after entry revealed extensive infiltration of the upper lobes bilaterally with marked pulmonary shrinkage on the right side displacing the mediastinal structures. A homogeneously distributed nodular peribronchial infiltration was present throughout both lungs.

It was felt that the patient could receive convalescent care at home and he was discharged eleven days after entry. Before discharge he was given 500 cc. of citrated blood which was well tolerated. At time of discharge his white blood cell count was 73,600 per cubic millimeter with 70 per cent lymphocytes and the red cell count was 4.12 million per cubic millimeter. A roentgenogram of the chest taken on the day of discharge showed a marked decrease in the transverse diameter of the heart from 13 cm. to 10.3 cm.

The patient was confined to bed at home. He was orthopneic and continued to have a productive cough and septic fever. He died September 14, 1946, seventeen days after discharge from the hospital.

**Clinical diagnosis** miliary tuberculosis far advanced pulmonary tuberculosis lymphocytic leukemia arteriosclerotic heart disease

*Necropsy*

Gross examination revealed the body of an emaciated male. No lymph nodes were palpable. The right pleural cavity was obliterated because of adhesions. The trachea was deviated to the right and the lymph nodes of the mediastinum showed enlargement and pigmentation. The heart weighed 320 grams and the coronary vessels were patent throughout.

The right lung weighed 890 grams, the left 1010 grams. On the cut surface they revealed marked fibrosis with grayish white infiltrations 1 to 3 mm in diameter throughout the parenchyma. The right upper lobe revealed a small cavity 1 cm in diameter.

The spleen weighed 300 grams. On section the corpuses were well defined, but there were diffuse gray infiltrations throughout the pulp measuring up to 3 mm in diameter.

The liver weighed 1830 grams and on section showed occasional whitish areas among the otherwise normal parenchyma. The kidneys were of normal size and architecture. Numerous pinhead gray areas were spread throughout the cortex. The same type of infiltration was noted in the sections of the adrenals.

The abdominal and mesenteric lymph nodes were enlarged. The bone marrow was pale but not remarkable otherwise. No other gross abnormal findings were noted.

*Microscopic Examination*

**Lungs.** The bronchi and bronchioles were dilated and showed peribronchial fibrous proliferation. An occasional conglomerate tubercle with central caseation and surrounding fibrous reaction was noted. Within a dilated vascular channel a mass of tuberculous granulation tissue was seen and suggested a possible source of the miliary spread. In the alveoli surrounding the early conglomerate masses of tubercles proliferating fibroblasts and epithelioid cells were seen. In addition to the older process, there was a widespread distribution of single or multiple young tubercles with little surrounding fibrous reaction.

**Spleen.** The parenchyma was largely replaced by tubercles showing minimal central necrosis and containing giant cells. In the scanty uninvolved areas there was no obliteration of the sinusoids which contained many lymphocytes, large mononuclear cells, and a few red blood cells. A moderate epithelioid hyperplasia was noted. The rare germinal centers were distorted and replaced in part by young and old lymphocytes and many mononuclear cells.

**Liver.** The hepatic lobular pattern was well maintained. The sinusoids were distended but contained few cells. These were chiefly red blood cells. There were few lymphocytes, monocytes, or polymorphonuclear cells. Throughout the parenchyma young and old tubercles could be discerned. These contained giant cells and showed slight necrosis. Immediately adjacent to the tubercles, particularly in the periportal connective tissue, were large numbers of mature lymphocytes.

**Kidneys.** Several areas contained tubercles with central necrosis. Other areas showed large conglomerate portions of tissue with widespread caseation and a marked lymphocytic infiltration at the border. The intervening glomeruli and tubules appeared normal.

**Lymph nodes.** Bronchial and mesenteric nodes showed preservation of the normal architecture with a marked hyperplasia of the reticulo-endothelial pattern. The sinusoids were intact and contained many lymphocytes and mononuclear and plasma cells. Tubercles were widely scattered among the intact lymphoid follicles. These were usually small without caseation but showed marked giant cell formation. No capsular invasion nor abnormal number of mitoses was seen (figure 2).

**Bone marrow.** Several sections of sternal and vertebral marrow revealed extensive single and conglomerate tubercle formation with marked caseation and trabecular bone destruction. Aside from the tubercle formation there was a normal quantitative and qualitative relationship of the myelopoietic and erythropoietic series. Megakaryocytes were present in adequate numbers (figure 3).

**Miscellaneous.** Sections of the adrenals showed diffuse tubercle formation in the cortex and medulla with dense fibrous replacement. Studies of the thyroid, pancreas, gallbladder, testes, and prostate showed no changes of significance.

**Anatomic diagnosis.** (1) Bilateral pulmonary tuberculosis, fibrocaceous type, with cavity of right apex and diffuse right pleural adhesions. (2) Miliary tuberculosis of lungs (bilateral), liver, spleen, adrenals, lymph nodes, and bone marrow. (3) Reactive lymphoid hyperplasia of lymph nodes. (4) Lymphocytic leukemoid reaction of bone marrow. (5) Generalized arteriosclerosis with moderate coronary sclerosis and focal myocardial fibrosis.

FIG 2—CASE 2, LYMPH NODE ( $\times 120$ ) Typical section of the diffuse tuberculous invasion. Diffuse hyperplasia with intact capsular wall present (lower right corner)

FIG 3—CASE 2, BONE MARROW ( $\times 120$ ) The epithelial process is surrounded by marrow of normal architecture

## DISCUSSION

Both of these cases were diagnosed as lymphocytic leukemia when first seen by members of the Hematology Unit. It was not until necropsy that the question of a leukemoid response to tuberculosis arose. Krumbhar<sup>11</sup> has stated that it may not be possible to distinguish between a terminal leukemoid blood picture and a true leukemia. Such was true in these case studies.

In Case 1, the miliary tubercles showed a fine necrotic matrix with no proliferation of fibrous tissue. The entire process consisted of massive necrosis and the diagnosis of miliary tuberculosis was made by demonstrating acid-fast organisms in these areas. These lesions were similar to those described by Leibowitz<sup>9</sup> and Coley and Ewing.<sup>8</sup>

The report by Leibowitz<sup>9</sup> includes a review of the literature (especially European) of the necrotic lesions in tuberculous sepsis. One case reported by Marzullo and DeVeer<sup>4</sup> revealed no epithelioid changes at autopsy, but rather necrosis. On entry to the hospital this patient had a white blood cell count of 57,000 with 15 per cent myeloblasts. He died of tuberculous pneumonia.

Rich and McCordock<sup>12</sup> observed in animal experiments some correlation between the number of organisms and the extent of necrosis. The presence of extensive necrosis is probably correlated with the number of bacilli present. Upon reviewing their cases, these authors noted that acid-fast organisms were more numerous in the soft tubercles with extensive necrosis. In the more proliferative tubercle, the organisms were sparse. The soft tubercle is probably the result of a massive infection of the blood stream associated with a high degree of allergy.

Such a condition probably existed in Case 1. A long-standing tuberculous infection in the neck was associated with a miliary sepsis. Can we consider the lymphocytic leukemoid picture to be an agonal response to the infection? The interesting study of Wiseman and Doan<sup>13</sup> may aid in understanding the lymphocytic response. These authors showed that the age of the lymphocyte can be determined by progressive variations in cellular cytology, namely, basophilia of the cytoplasm, chromatic density, and distribution of the non-segmented nucleus. They divided the circulatory lymphocytes into three classes—young, mature, and old cells. It was observed in rabbits that there was a marked increase in the percentage of young lymphocytes following infection by intravenous injection of avian tuberculosis bacilli. As the animal neared death from miliary tuberculosis, there was a sharp decline in the percentage of mature forms. Studies of clinical material also showed an increase in young lymphocytes with progression of pulmonary tuberculosis. The authors felt that the increase in young lymphocytes with tuberculosis infection indicated that these blood elements were utilized in the pathologic process.

From this study can we postulate that a marked stimulus of the tuberculotoxins shifted the response of the lymphocyte to the early stem forms? This might help explain the genesis of the lymphocytic leukemoid blood picture in the first case.

Case 2 presented a more controversial problem. In a patient of this age, with an illness of long duration and an elevated white blood cell count, the diagnosis of chronic lymphocytic leukemia was more tenable. It was believed when this patient was first studied that a chronic leukemia had activated an old fibrotic tuberculosis

and that this was associated then with a diffuse hematogenous peribronchial extension culminating in cardiac embarrassment from a subacute cor pulmonale. The tender hepatomegaly and splenomegaly were first noted when the patient entered the hospital with cardiac embarrassment. This patient had been observed by a staff hematologist regularly for five months before entry, and at no time did he note adenopathy or hepatosplenomegaly.

Rossle<sup>14</sup> has observed patients with lymphocytic leukemia without adenopathy or hepatosplenomegaly. However, microscopic examination of the bone marrow in these cases revealed leukemic infiltration. In the second of our cases, necropsy findings of young and old tubercles throughout the organs and lymph nodes suggest a repeated bacteremia. Can we postulate that this patient had a persistent leukemoid reaction for six months before death? In a study of leukemoid reactions, Hill and Duncan<sup>15</sup> recently reported a case of leukemoid reaction which existed over a three year period in a 40 year old Negro male who had been followed in a leucic clinic. The white blood cell count varied from 23,000 to 78,400 per cubic millimeter of blood, and of these, 3 per cent were myeloblasts and 25 per cent myelocytes. Autopsy revealed a suppurative osteomyelitis of the sacrum associated with a gangrenous, necrotic abscess of the right thigh and an abscess of the right posterior lung field. In a similar manner, a persistent lymphocytosis might allow us to explain the blood findings in this case as a result of persistent irritation of the lymphoid tissue and marrow. Feldman and Stasney<sup>16</sup> have suggested an allergic response of the bone marrow to explain the myelocytic leukemoid blood response in tuberculous rabbits receiving tuberculin injections. We know of no experimental work showing lymphatic leukemoid response to tuberculin to indicate that lymphocytosis to the extent observed in these patients may be an allergic response to miliary tuberculosis. However, the lack of any evidence on microscopic examination of leukemic infiltration in the tissues in Case 2 forced us to conclude that the elevated white blood cell count of mature lymphocytes was the response to a progressive miliary tuberculosis.

Muller<sup>1</sup> has commented on the rarity of the leukemoid reaction. During a five year period in which approximately 2000 patients with tuberculosis were observed, no leukemoid blood pictures were seen. In rare cases, a few myelocytes were seen, and no case showed over 3 per cent myelocytes.

#### SUMMARY

Two cases of miliary tuberculosis that were diagnosed clinically as lymphocytic leukemia are presented. Both cases had evidence of chronic tuberculosis which was of 43 years' duration in Case 1 and of 28 years' duration in Case 2. Both patients had granulocytopenia and anemia.

Autopsy findings revealed no evidence of leukemic infiltration, but a diffuse miliary tuberculosis, involving all of the hematopoietic tissues, existed in both cases.

## EDITORIAL

### WHAT'S IN A NAME

SEVERAL statements have appeared recently<sup>1 2 3</sup> concerning standardization of hematologic nomenclature. Their purpose is to bring clarity where there is confusion, uniformity where there is variety and order out of chaos. It is proposed that no new ideas be introduced but that terms be accepted which everyone will use in an agreed-upon sense, and that tables be made available in which a list of corresponding terms which are to be outmoded will be presented.

These statements reflect the considered views and sincere efforts of a number of individuals, to whom due credit must be given. The devotion of the chairman of the committee on nomenclature, which is the source of these reports, certainly deserves respect. It must be pointed out, however, that, although the published material gives the impression that the proposed nomenclature is desirable and widely supported, the contrary opinion is substantial and significant but has mainly found expression in informal conversations of persons interested in the field.

It can be admitted that hematologic terminology is confusing. However, there is reasonable doubt that the new proposals will improve matters. What is to be achieved by naming the stage of leukocyte preceding the myelocyte a progranulocyte when most people understand quite clearly what is meant by the term, promyelocyte? Will an official stamp have value by affixing an erroneous interpretation to the stab cell? Does a student gain a better understanding of physiology by being forced to call something a cell which is not one, such as the red corpuscle and the platelet, for which the terms erythrocyte and thrombocyte, respectively, are proposed? True, these terms are in current, though erroneous, use. But why endorse errors with a stamp of approval?

These, however, are comparatively minor criticisms of the proposed nomenclature. The recommended terminology for the red cell series impresses one as being artificial to an extreme. In an attempt to use corresponding classifications for the leukocytic and erythrocytic series of cells, differentiation is centered about nuclear rather than cytoplasmic features. As a consequence, a prorubricyte stage is introduced which can scarcely be differentiated, if at all, from the rubriblast. The concept of distinguishing cells of the normal erythrocytic series chiefly on the basis of cytoplasmic maturation, though simple and generally accepted, is replaced by a proposed differentiation which would be most difficult to follow. Thus, an attempt at orderliness is likely to bring confusion instead.

It is difficult to escape the conclusion that the recommended terminology would only add to the terms that the student must learn and would increase verbiage where there is sufficient already. No one will be better off in reading literature

\* For another editorial on *Names for Blood Cells* see *Lancet* 1: 486 (March 19) 1949

published hitherto and there will still be debate as to whether a given cell is one thing or another

Differences in terminology have arisen mainly because of differences in interpretation of observations made under a variety of conditions. It is reasonable to expect that as new knowledge is gained, agreement will come naturally as there is better understanding. Terms may then be modified by the normal process of evolutionary selection rather than through arbitrary definition. Emphasis, in short, should be placed on advancing knowledge rather than in too much concern about names.

Since the new terminology is not readily and wholly acceptable, nothing can be gained by its introduction at this time. Haste will but make more difficult the acceptance of terms which time and repeated discussions of all those concerned, including interested individuals in all English-speaking countries, might make possible in the future.

MAXWELL M. WINTROBE, M.D.

#### LETTERS TO THE EDITOR

##### TO THE EDITOR

In the January issue of *Blood* a condensation of the first two Reports of the Committee for Clarification of the Nomenclature of Cells and Diseases of the Blood and Blood Forming organs was published. Since I am not convinced of the soundness with which this unilateral approach has been conducted, I would like to bring certain things to your attention.

Hematology is international in its scope and as a consequence its terminology is not the property of any one country. As in other scientific disciplines, the ultimate goal of uniformity in nomenclature is certainly one which is desired by all. It is for this very reason that the constitution of the International Society of Hematology lists one of its purposes— to attempt to standardize on an international scale hematologic methods and nomenclature.

Such an undertaking would undoubtedly enlist not only the services of clinical pathologists, but also those of embryologists, histologists, physiologists, zoologists, tissue culturists, immunohematologists, and others whose work might be influenced by an alteration in hematologic terminology. The approach must be multilateral from the start. Groups serving on this committee should be provided with extremely accurate illustrations of cells under discussion. Furthermore, these illustrations should include the range of variability of cell types.

This is not the first attempt by Americans to alter terminology. As a matter of fact, some of the confusion which is disturbing at the present time is the primary fault of American hematologists. In 1915 Doan, Cunningham and Sabio with very good intentions wrote. The terminology in hematological literature has become so confused, different investigators using the same designation for wholly different histological entities or the same histological entity being designated by a variety of terms, that it becomes necessary to define the limited sense in which certain names already in the literature will be used in this paper. Then in the case of erythropoiesis, they disregarded this by using the term megalo-blast in a manner quite different from its accepted usage by such leading hematologists of that period as Downey, Ferrata, Maximow, and Naegele. Additional confusion in American hematology was created by Peabody's unequivocal acceptance of Doan, Cunningham and Sabio's theory and by Isaacs and Osgood propounding theories of a similar nature. It is unfortunate that Doan, Cunningham and Sabio advanced

their theory for avian and mammalian erythropoiesis during a period when so much emphasis was being placed on the pathologic physiology of blood forming organs. If one takes time to read British, French, German, Swiss, Italian, Scandinavian and Latin American contemporary hematologic literature, it soon becomes apparent that Doan et al., Isaacs and Osgood have placed certain phases of American hematology in a very bad light.

For some time Europeans, Latin Americans and some Americans have recognized the inadequacy of the theory for red cell genealogy as proposed by Doan et al., Isaacs and Osgood. Apparently Osgood too recognizes that something is amiss and believes it can be rectified by avoiding certain terms like the megaloblast, for example. The importance of this cell type is more clearly understood in Europe today than it has ever been before. In order to illustrate this importance, consider the following from an unpublished manuscript:

"The megaloblast problem has many ramifications which affect, in varying degrees, the thought in quite a few branches of medical science. Zoologists who do research in comparative hematology have pointed out that megaloblasts and the first circulating mammalian embryonic red blood cells should be called ichthyoid, since they resemble the permanent red cells of fish and amphibians. The embryologist is interested in whether or not these cells are present only in the yolk sac during the prehepatic period of embryogenesis, or whether they are also found in the embryonic liver, spleen and bone marrow. They would also like to know whether the embryonic and pathologic red blood cells are identical. Some histologists teach that megaloblasts, derived from endothelium of the adult, are present in normal bone marrow and act as normal precursors for definitive erythrocytes, whereas other histologists consider that they belong quite definitely to the realm of pathology. In the latter, many general clinical pathologists maintain that the presence of megaloblasts are pathognomonic for all liver principle deficiency anemias, while, on the other hand, some do not consider their presence unusual in any type of anemia. Experimental pathologists and internists have been attempting to produce in laboratory animals a condition which would simulate pernicious anemia of humans and some have purported to have produced a megaloblastic bone marrow. Some physiologists consider that these cells function as the first hemoglobin synthesizing units under normal conditions and the biochemists are confronted with the problem of determining whether or not hemoglobin is identical under all conditions. Pharmacologists, who are interested in the bioassay of antipernicious anemia preparations, would like to know whether or not megaloblasts are the only red cells which will respond in the presence of these substances. Furthermore, they are also concerned with determining what portions of specific molecules of these substances will cause megaloblasts to disappear from the marrow of pernicious anemia patients. They also ponder the question of why all patients with a megaloblastic marrow do not respond to the same specific therapy. Some clinicians are interested in the megaloblast problem because the presence of such cells in a patient's marrow indicates to them a need for the administration of specific therapy which, in most cases, must be maintained at an optimal level throughout the remainder of the patient's life. And, needless to say, the absence of these cells from the sternal marrow of a patient with severe anemia affords the rationale for an entirely different therapy. Lastly, the hematologist has at least a theoretical interest in many, if not all, of these phases pertaining to the megaloblast problem.

To some it may seem that all of this is so much hogwash and that the difficulty might be solved readily by a change in terminology. Therefore, let us cast aside all hematologic terminology and designate the earliest cell recognizable as a hemoglobin synthesizing unit as red cell No. 1. The next step would be to study this cell under embryonic, fetal, normal adult, pathologic and experimental conditions, determining the morphologic features of its nuclear pattern and cytoplasm. If red cell No. 1 has the same attributes under all of these conditions, then we are justified in selecting the most appropriate term as a label for all. On the other hand, if red cell No. 1 differs under embryonic, normal adult and certain pathologic conditions, we would not be justified in grouping all of these cells together. In addition to this, if there are constant morphologic differences, then cytochemical, physiologic and biologic studies should be made to determine the underlying basis for them. Since there are morphologic and other differences between some of these cells, they should be called red cell No. 1 under embryonic conditions, red cell No. 1 under normal adult conditions, and red cell No. 1 in liver principle deficiency anemias during relapse. In the latter instance, it has been appropriate to refer to these cells as megaloblasts because that term—good or bad—was first applied to them by Ehrlich in 1880.

Just for the sake of argument, let us assume that the proposed terminology has been accepted by all. Will it change the megaloblast normoblast problem? No, it will not! In its place some American clinical hematologists and pathologists will continue to recognize morphologic differences between a pernicious anemia type prorubricyte and a rubriblast and others will not. The problem will remain just so long as some American hematologists either fail to recognize minute but constant differences in nuclear pattern or fail to interpret them properly.

The proposed terminology for red cells might have done better by utilizing good Anglo-Saxon terms like large, medium and small. The proposed terms of rubriblast and prorubricyte are regrettable in that they are hybrid. A Latin-Greek red cell gives rise to a Greek red cell. However, it is consoling to know that megalocytes are not to be avoided and that it is possible for them to come from metarubricytes. The suggested terminology will result in one more complex than existing ones, for example, megaloblasts become pernicious anemia type prorubricytes. In anatomic nomenclature there is a tendency to avoid cumbersome terms and not create them. Why should, for example, the pectineal part of the inguinal ligament be used when lacunar ligament is available?

In conclusion, it is generally recognized that problems of nomenclature or classification become less complex when more is learned about the various attributes of the subject in question. Anatomists have more than a casual interest in hematologic nomenclature because they are responsible for teaching embryology and histology to medical students. It would be very unfortunate to teach two terminologies—one for preclinical and the other for clinical courses.

Oliver P. Jones  
Professor of Anatomy,  
The University of Buffalo, School of Medicine

Dr Wintrobe's Editorial and Dr Jones' letter were referred to Dr E. E. Osgood, who replied as follows:

#### TO THE EDITOR

Both Doctor Wintrobe and Doctor Jones admit a state of confusion in definitions and terminology has existed in the field of hematology. Their criticisms, which are not clearly answered in the reports of the Committee, condense to the following four statements:

1. *Next year we will know more, therefore we should wait.*

*Answer:* This has been and will always be true. If we were to wait until all is known or until 100 per cent agreement is reached, nothing would ever be done.

2. *They and some others criticize the term progranulocyte, the terms selected for the erythrocytic series and the qualifying adjective phrase, pernicious anemia type.*

*Answer:* It is admitted that promyelocyte would be more consistent with other terms selected for cells of the granulocytic series. However, the Committee recommended the term, progranulocyte, because the definition accompanying it excludes cells containing neutrophilic, eosinophilic or basophilic granules. The term promyelocyte has been used for cells variously defined as containing 10 per cent, 30 per cent or 50 per cent of their full quota of such granules, and these are lines of division between stages of differentiation which two observers cannot exactly duplicate.

The definitions and terms in current use for the erythrocytic series were fully discussed at each of three meetings and the recommended terms resulting were agreed on as being the best solution to an admittedly difficult problem. The question is not, "Is this solution ideal?", but is rather, "Can anyone suggest a better solution?" General agreement on *one* definition and *one* term for each cell stage is more important than the particular term selected. These were the terms and definitions recommended. Agreement is more easily reached around a conference table, so it seems most unfortunate that neither Dr. Jones nor Dr. Wintrobe found it possible to attend any of the Committee meetings to which they were invited. Dr. Hal Downey, whom Doctor Jones mentions in his letter, was present at the meetings and fully concurs in the recommendations. The 30 members of the Committee who have approved the recommendations of the second report include competent men in most of the fields mentioned in Doctor Jones' letter. During some of the meetings, atlases of hematology as well as blood and marrow smears

and microscopes were available to all discussants so that morphologic differences and similarities could be visually evaluated during the process of reaching agreement for recommended terms and definitions

Both letters imply that use of these terms binds one to a particular theory. One of the most fundamental principles guiding Committee decisions and emphasized in the reports has been to avoid any attempt to settle around a conference table anything which could be settled only by investigation. If anyone wishes to teach his students that a polychromatic erythrocyte is less differentiated than a normochromatic rubricyte he can express that opinion clearly in this recommended terminology.

One of the major weaknesses of other terminologies has been that they failed to distinguish between stages of differentiation and the disappearance of ribonucleoprotein with simultaneous appearance of hemoglobin in the cytoplasm. With the recommended terms both can be clearly indicated. Dr Wintrobe pleads for more consistency in the terms for the granulocytic series but would retain the suffix *-blast* in the erythrocytic series for a cell with a pyknotic partially extruded or partially autolyzed nucleus which does not fit the criteria for any other *blast* stage. One needs to ask but one question regarding the term pernicious anemia type versus megaloblastic. Even if megaloblastic had only one definition would it not be clearer to the student of medicine studying it for the first time to learn about pernicious anemia type granulocytes and pernicious anemia type marrow picture than about a megaloblastic marrow picture? Certainly one could not speak of megaloblastic granulocytes yet the morphologic changes are just as striking as those in the erythrocytic series.

### 3 *A special atlas is necessary*

*Answer.* If the definitions are carefully read—and these definitions are just as important as the terms—it will be seen that the criteria for differentiation of the stages are clearly illustrated in every atlas of hematology that has ever been published. The Committee clearly recognizes that all subdivision is arbitrary and that an infinite number of subdivisions would be possible. They selected that number of subdivisions which in their experience was clinically and diagnostically useful and tried to phrase definitions that would put the same cell in the same category when seen by different observers, but made provision for as much further subdivision through the use of modifying adjectives as might be needed for any investigative purpose.

### 4 *The recommendations should be international before they are published*

*Answer.* The problem seems sufficiently difficult to settle in one language at a time. It is the sincere hope of the Committee that other language groups will form similar committees and that they will give serious consideration to the advisability of selecting the same definitions at least and to achieving a comparable nomenclature.

The other points raised in the two letters are clearly answered in the text matter of the reports of the Committee. The Committee reports were circulated before publication to all Committee members whether or not they were in actual attendance at meetings. These published reports<sup>1, 2, 3</sup> represent the combined efforts of a number of persons with the approval of the majority of the members of the Committee; they are not the recommendations of any one individual.

The terms to be avoided are not synonymous in most instances with the term to be used. They are merely terms that have been used by some for the cells included under the terms recommended and defined in the reports. The Committee reports are *recommendations* only and provision has been made to review and revise terminology periodically. It is not to be expected that they will receive 100 per cent acceptance in areas where scientific freedom exists. A statistical analysis of the response to the recommended nomenclature which has been received by Committee members and the American Society of Clinical Pathologists has not yet been made, but it will be brought into presentable form and the result will be made public in a future Committee report.

In conclusion it is felt that to debate the values of any nomenclature in the scientific press can result only in the amassing of a large body of print and a loss of considerable time. The interested reader of these letters should be referred to the published reports of the Committee for therein are included all of the purposes and guiding principles. If the recommended nomenclature has merit it will be used if it lacks merit it will atrophy from disuse. The present indications—obtained from verbal comments and letters—are that the recommended terms and definitions are being widely adopted.

As stated in the Committee reports the primary purpose of this Committee has at all times been to clarify hematologic terms for the benefit of the medical profession as a whole and future students of medi-

cine and related sciences, rather than for the relatively small proportion of the present medical profession which devotes most of its time to hematology

For the Committee for Clarification of the  
Nomenclature of Cells and Diseases of  
the Blood and Blood Forming Organs

A subsequent letter received from Dr. Jones indicates that he was unable to attend two of the last meetings, and that he does not agree on all points with the report. The following letter on the subject was received from Dr. Frank H. Bethell:

#### TO THE EDITOR:

The statements of the chairman of the Committee on Classification of Nomenclature of Cells and Diseases of the Blood and Blood Forming Organs made in answer to the criticisms of Doctors Jones and Wintrobe have my whole-hearted endorsement. I believe that the publication of these letters will serve a useful purpose if it leads to a broader understanding of the objectives and achievements of the Committee. As Dr. Wintrobe says, the opposition to the recommendations of the Committee has been expressed for the most part in informal conversations. My participation in some of these discussions has convinced me that the discussants, with few exceptions, have not been well informed on the content of the Committee's reports. I should like to urge that every interested person, before he takes a position in this controversy, read carefully the published reports of the Committee with particular attention to the definitions.

FRANK H. BETHELL, M.D.  
University of Michigan, Thomas Henry Simpson  
Memorial Institute for Medical Research

#### FURTHER COMMENT ON NOMENCLATURE DISCUSSION

From the vantage point of the Editorial chair, there seems to be a good deal of merit in both points of view regarding the proposed revision and systematization of hematologic nomenclature. Although faint echoes are heard in this discussion of the frequently polemic articles which were seen in *Folia Haematologica* years ago, it can be stated that the proposed system of nomenclature, as worked out by a serious group of well-intentioned observers, is not only in the interests of simplicity, but slanted frankly for the students and the younger generation of physicians. Although some of us may dislike to have terms changed or systematized, many of

the younger men in the field have evidently taken to the newer terms without too much difficulty, even to the seemingly outlandish ones of rubricytes and the like. Certainly, consistency is always something to be applauded so why not use for leukemia the terms myelocytic, lymphocytic, and monocytic rather than *myelogenous*, *lymphatic* and *monocytic*? It is admittedly easy to slip into this particular consistency but on the other hand, one finds it hard to take to one's bosom the rubriblast or to understand the actual need for its use. Therefore, it is good to note Dr. Osgood's statement that the proposed system of nomenclature is by no means rigid and that by a process of selection the fundamentally correct and the simple terms will be retained and the wrong and the difficult ones will atrophy from disuse. The members of the Committee are to be congratulated for the vast amount of time and patience they have spent around the conference table. They are doubtless correct in having obtained the impression that some of their critics might have been less critical had they spent some time with them in discussing their problems. In any event, there can be little doubt that out of all this great effort, at least some good will ensue to the innocent bystander in hematologic nomenclature.

WILLIAM DAMESHEK, M.D.

## BLOOD COAGULATION

STABILITY OF PROTHROMBIN AND AC-GLOBULIN IN STORED HUMAN PLASMA AS INFLUENCED BY CONDITION OF STORAGE J L Faley A G Watt and W H Stegers From the Department of Physiology Wayne University College of Medicine Detroit Michigan Am J Physiol 154 122-133, 1948

Normal plasma has been shown to contain, among other things a globulin factor which affects the transformation of prothrombin to thrombin—a plasma accelerator substance called Ac globulin. The present report concerns the stability of this substance and of prothrombin itself under various conditions. Under specific conditions human venous blood was drawn into citrate or oxalate anti-coagulant mixtures and then after a variety of manipulations (centrifugation at various speeds storage for various periods of time use of various concentrations of oxalate or citrate) tested for the amounts of contained prothrombin and Ac globulin.

For testing purposes Ac globulin was determined by a previously described method in which prothrombin, thromboplastin and calcium are present in controlled amounts, so that the rate of thrombin formation measures the amount of Ac globulin. The amount of prothrombin was determined (1) by a standard two-stage method in which saline appears as a diluent and (2) by a modified two-stage method in which saline is replaced by bovine serum (containing of course Ac globulin).

In both oxalated and citrated plasma the prothrombin activity did not change for a period of several days. After this period, the original two-stage method detected a progressive fall in prothrombin. However by the modified method—in which Ac globulin was added—the amount of prothrombin was still unchanged for as long as fifty-six days. It seemed obvious therefore that the apparent fall in prothrombin was illusory and that the fall was due to a loss of Ac globulin and not prothrombin itself from the stored plasma. In addition the apparent (illusory) prothrombin fall occurred earlier and was more marked in oxalated than in citrated plasmas i.e., Ac globulin was less stable in oxalated than citrated blood.

In a further experiment a sample of oxalated plasma which originally had a prothrombin content of 290 units/cc was found after 53 days of storage to have an apparent prothrombin content by the original two-stage method of 19 units/cc. When this determination was modified by the addition of (a) bovine serum or (b) pure Ac globulin, or (c) an extract of bovine platelets then the prothrombin content was found still to be 290 units/cc. It thus seems that not only serum but also platelets, contain a prothrombin accelerating substance. However platelets were also found to contain a factor which decreased the stability of Ac globulin, this factor was apparently operative after the platelet Ac globulin supply had been dissipated (24 hours of storage).

These and further similar experiments will compel revision of the simple schemata of blood coagulation. It seems likely however that the plasma, serum, and platelet Ac globulin substances (which are similar) are the same as Quick's prothrombin A and as Owren's factor V and that they play an important role during the initial stages of coagulation.

S.E.

CONCENTRATION OF PROTHROMBIN AND AC-GLOBULIN IN VARIOUS SPECIES *R C Murphy and W H Siegers* From the Department of Physiology, Wayne University College of Medicine, Detroit Michigan. *Am J Physiol* 154 134-139 1948

The authors determined the concentrations of prothrombin and Ac globulin in the bloods of various animals, including man and noted that there was a wide variation from species to species. For example, it was found that although the plasma prothrombin content in dogs man and guinea pigs was the same (200 to 300 units/cc) the plasma Ac globulin of the dog measured 150 units/cc that of man 12 units/cc and that of the guinea pig 30 units/cc. Since the Quick one-stage method of prothrombin estimation measures not the amount of prothrombin but the amount of prothrombin plus the rapidity of its conversion to thrombin (this conversion depends to a large degree upon Ac globulin) it can be seen that the differences in various species between the one stage and the two-stage methods of prothrombin determination may well be due to the marked variations in concentration of Ac globulin in various species. Thus dog, man and guinea pig have identical prothrombin contents (two-stage method) but widely divergent prothrombin times (one stage method) due probably to the different Ac globulin concentrations found.

Man has a low plasma Ac globulin activity, and therefore a relatively high ratio of prothrombin to Ac globulin. Hence the authors suggest, there may be a relatively narrow margin of safety beyond which hypoprothrombinemia may occur.

S.E.

PLATELET EXTRACTS, FIBRIN FORMATION AND INTERACTION OF PURIFIED PROTHROMBIN AND THROMBOPLASTIN *A G Ware J L Fabry and W H Siegers* From the Department of Physiology Wayne University College of Medicine Detroit Michigan. *Am J Physiol* 154 140-147 1948

Analysis of extracts of bovine platelets led to a revision of the relatively naive concept that platelets initiate blood coagulation by the liberation of initial amounts of thromboplastin. Actually a small amount of thromboplastin was found in platelets, but it was only a very small amount. In addition two other substances were present: (1) an Ac globulin type of substance and (2) a new factor called platelet factor 2.

1. Platelet extract was found to contain something which accelerated the conversion of prothrombin to thrombin in the presence of thromboplastin and calcium. This substance acted similarly to serum Ac globulin and was quantitatively identical with serum Ac globulin in its ability to convert prothrombin into thrombin. In addition platelet Ac globulin and serum Ac globulin were both similarly precipitated by half saturated ammonium sulfate and were both destroyed by heating to 53 C. On the other hand there was a difference between the two substances in their length of stability at 53 C. and more dramatic, only platelet Ac globulin could be sedimented in the ultracentrifuge. Hence it was concluded that platelet Ac globulin and serum Ac globulin are probably two different proteins with similar prothrombin activating activities. The authors estimated that some 5 per cent of the total accelerator activity comes from the platelets.

2. Platelet extracts were found to contain a previously undescribed action or substance which hastened the action of thrombin on fibrinogen. The factor was inferred from the following type of data:

thrombin + fibrinogen = clot in 16 seconds
platelet extract + thrombin + fibrinogen = clot in 11 seconds
platelet extract + fibrinogen = no clot in 10 minutes

This substance was rapidly diluted out. It is still under investigation.

It is pointed out that neither serum Ac globulin nor platelet Ac globulin is absolutely necessary for the production of thrombin; these substances apparently act merely as catalysts. A detailed schema is presented in which the roles of these accelerator substances in the initial stages of coagulation is incorporated. The schema of course is still speculative.

S.E.

PROTHROMBIN CONVERSION FACTOR OF DICUMAROL PLASMA. *C A Owen and J L Bollman* From the Division of Experimental Medicine, Mayo Foundation, Rochester Minnesota. *Proc. Soc. Exper Biol & Med* 67 231-234, 1948

Data obtained from experiments on dicumarolized dogs suggests that the hemorrhagic diathesis produced by dicumarol is attributable not alone to a disappearance of prothrombin but also to the loss of a factor, the function of which is to facilitate the conversion of prothrombin to thrombin. Variations in the concentration of this conversion factor present in plasma serum or serum pseudo-globulin may explain the familiar discrepancies in the results of one and two-stage methods of estimating prothrombin activity. It may also account for the therapeutic efficacy of serum in the treatment of cattle with sweet clover disease, a phenomenon otherwise difficult to explain.

C. P. E.

ACTION DE LA PHENYL-INDANE DIONE SUR LE TAUX DE LA PROTHROMBINE I. ETUDE EXPERIMENTALE SUR LE LAPIN J. P. Soulier and J. Guiguen II. UTILISATION EN CLINIQUE HUMAINE (EFFECT OF PHENYL-INDANE DIONE ON PROTHROMBIN LEVELS I. EXPERIMENTAL STUDIES ON THE RABBIT II. USE ON HUMANS.) J. Guiguen and J. P. Soulier *Rev. Hemat.* 3: 180-195, 1948.

In the first series of experiments using 16 rabbits, the authors found that phenyl indane-dione (P.I.D.) had a very marked effect on prothrombin level. Doses of 10 to 20 milligrams per kilo produced a decrease of prothrombin to a level of 30 to 40 per cent, this effect being reached before the eighteenth hour. There was no modification of platelets clot retraction or fibrinogen level. Higher dosage did not produce greater hypoprothrombinemia and the authors did not find any hemorrhages even with a dosage ten times the standard dosage. The lethal dose was well over 600 mg./kilo which gave a very high safety margin. Histologic examinations of the rabbits given very high doses of P.I.D. (under 400 mg./kilo) did not show histologic injuries.

The P.I.D. was used in the prevention of thrombosis in 43 women after pregnancy. In all these cases doses of 10 to 20 mg./kilo yielded a very constant decrease of prothrombin level. The decrease began earlier than with dicumarol about the twelfth hour and the full effect was obtained between the twenty-fourth and the forty-eighth hour which is a 30 to 40 per cent level. Return to a normal level was quite constant and 100 per cent prothrombin was reached by about the ninety-sixth hour.

This constancy in the chronology is very different from that observed with dicumarol. Individual susceptibility to the drug seems also to be less important than in the case of dicumarol.

In 2 cases, the P.I.D. was given to patients with known thrombophlebitis (every 3 days 10 mg./kilo). This dose was effective in controlling the prothrombin level around 30 per cent. The patients' state was in both cases favorably affected. In the 41 cases where the drug was given prophylactically, no phlebitis was observed.

In contrast with these advantages the complete inactivity of vitamin K<sub>2</sub> even in huge doses and even when given prior to the administration of the P.I.D. must be emphasized. But this fact is perhaps of minor importance since in no case was hemorrhage or hypoprothrombinemia of less than 10 per cent observed.

J. P. S.

THE RELATIONSHIP OF HEPARIN ACTIVITY TO PLATELET CONCENTRATION C. L. Conley, R. C. Hartmann and J. S. Lelley. From the Department of Medicine, Johns Hopkins University and Hospital, Baltimore. *Maryland Proc. Soc. Exper. Biol. & Med.* 69: 284-287, 1948.

To evaluate the significance of the reported increased susceptibility of thrombocytopenic blood to heparin (*Ann. Int. Med.* 27: 382, 1947) these investigators studied the clotting times of platelet free and platelet-rich plasmas prepared in silicone coated apparatus which were mixed in different proportions and contained graded concentrations of added heparin. The data presented justifies the conclusion that the magnitude of the clot inhibitory effect of heparin is inversely proportional to the number of platelets present and that the increased susceptibility of thrombocytopenic purpura blood to the action of heparin is attributable to the reduced platelet concentration rather than to a supplemental anticoagulant effect introduced by the presence of hypothetical heparin like substance. The results further suggest that the concentration of active heparin normally present in plasma is minute i.e. 0.0005 mg./ml. or less.

C. P. E.

CONCERNING THE RELATION BETWEEN PITUITARY ADRENOCORTICOTROPHIN AND THE CIRCULATING BLOOD PLATELETS M. A. Greer and B. R. Brown. From the Joseph H. Pratt Diagnostic Hospital and the Depart-

ment of Medicine Tufts Medical School, Boston Massachusetts Proc Soc. Exper Biol & Med 69 361-362, 1948

Since an increase in platelet concentration is usually found in the peripheral blood attending infection, trauma hemorrhage, and asphyxia, conditions which stimulate a release of pituitary adrenocorticotrophin (ACTH), the possible effect of the latter was tested in rats injected either with hog pituitary tissue or purified ACTH. A preparation of the latter was also given by repeated intramuscular injection to five human subjects including three normal individuals one male and two female, a young woman with hypopituitarism and another with thrombocytopenic purpura following an unsuccessful splenectomy. No change in platelet count was detected following these procedures. Moreover although pituitary ACTH is capable of causing a dissolution of lymphoid tissue with peripheral lymphopenia (Endocrinology 35 1, 1944), no reduction of circulating lymphocytes occurred in these experiments the only hematologic effect noted being a transient polymorphonuclear leukocytosis.

C.P.E.

THE CHEMICAL STATE OF THE CALCIUM REACTING IN THE COAGULATION OF BLOOD A. J. Quick and M. Stefanski From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wisconsin J Gen Physiol 32 191-202, 1948

For many years it has been generally accepted that ionized calcium is essential for coagulation. The use of amberlite which quantitatively removes calcium from the blood and other new techniques have been utilized by the authors to reinvestigate some of these problems. Sodium oxalate and citrate act in different manners. The oxalate not only precipitates ionized calcium but it also removes it from a compound which is essential for coagulation. Citrate combines with prothrombin and renders it inactive. The addition of magnesium or strontium restores the prothrombin to its original state. Studies of prothrombin activity under various types of condition have suggested the presence of a labile factor which is indispensable for coagulation and unstable in decalcified plasma.

O.P.J.

EFFECT OF AMINOPHYLLIN ON THE COAGULATION OF HUMAN BLOOD D. W. Blood and M. C. Patterson From the Department of Medicine Columbia University College of Physicians and Surgeons and the Medical Service of the Presbyterian Hospital, New York City, New York. Proc Soc. Exper Biol & Med 69 130-133, 1948

Experiments are reported which fail to confirm published reports ascribing to aminophyllin (theophyllin-ethylenediamine) a thromboplastic action with an accelerating effect on blood clotting which might predispose to intravascular thrombosis. Following the administration of aminophyllin orally or by vein no statistically significant changes were detectable in the clotting time or prothrombin activity of hospital patients with normal hepatic function and hematological findings.

C.P.E.

PROLONGATION OF ACTION OF HEPARIN J. J. Verzeletti, L. N. Sussman and M. J. Marder From the Medical Service Beth Israel Hospital, New York City, New York. J. A. M. A. 138 747-748 1948

In search for a form of heparin which might have a more prolonged action in the body than those currently available the authors devised a concentrated form of heparin (200 to 300 mg per cc of aqueous solution) emulsified in a mixture of cholesterol derivatives paraffin oil and beeswax. The use in this form of about 2 milligrams of heparin per pound of body weight resulted in satisfactory prolongation of the coagulation time for seventeen to twenty-four hours after a single injection. There were no toxic effects and no hemorrhagic phenomena with high coagulation times. According to the authors pain was negligible. Compared with this method the use of concentrated aqueous heparin increased the coagulation time for only six hours and the use of heparin dissolved in Pitkin's menstruum was associated with severe pain at the site of injection.

Although the authors list expensiveness as a disadvantage in the use of other forms of heparin they do not mention the relative cost of the current preparation.

## ERYTHROCYTE MORPHOLOGY AND PHYSIOLOGY

**THE STRUCTURE OF UNSTAINED RETICULOCYTES** *G Brecher* From the Pathology Laboratory, Experimental Biology and Medicine Institute, National Institute of Health, U S Public Health Service, Bethesda, Maryland *Proc Soc Exper Biol & Med* 69 89-90 1948

By means of phase microscopy, according to the author, it is possible to demonstrate the presence of intracellular granules and rods exhibiting Brownian movement, in unstained wet preparations of mouse blood diluted with hypotonic oxalate solutions. Similar findings were obtained on examining dried unfixed smears mounted in 10 per cent formalin or 1.2 per cent ammonium oxalate. The number of cells presenting these characteristics corresponded with the number of reticulocytes counted by routine methods. Moreover, their identification as reticulocytes was confirmed by the device of adding brilliant cresyl blue or new methylene blue to the oxalate diluent; these rods and granules being incorporated into stainable reticulum. Similar observations have been made in preliminary studies of human blood.

C P E.

**SIDEROCYTE COUNTS IN THE BLOOD OF NORMAL AND PREMATURE INFANTS** *H P Wright and D G Edmonds* From the Obstetric Unit, University College Hospital, London, England *J Path & Bact* 60 342-344 1948

Fifty normal full term infants and 7 premature infants were examined daily for the first 8 days of life. Parallel observations were made using the 2a' dipyrindyl staining technique and the prussian blue method. Reticulocytes were also counted. The percentage of granule containing cells (siderocytes) was very similar with both methods. The number in the blood of normal newborn infants gradually decreased during the first 8 days to approximate the value reported for normal adults. There was a rise of siderocytes from the second to fourth days in infants exhibiting physiologic jaundice. Premature infants had an even higher siderocyte percentage with the maximum occurring on the fourth day.

O P J

**VISCOSITY STUDIES OF ERYTHROCYTES FROM PERSONS WITH SICKLE CELL DISEASE** *W M. McCord, W H Kelley, P K Switzer and F B Culp* From the Departments of Chemistry and of Medicine, Medical College of the State of South Carolina and of Roper Hospital, Charleston, South Carolina *Proc Soc Exper Biol & Med* 69 19-22, 1948

The increase in blood viscosity attending the sickling of red cells previously demonstrated in cases of sickle cell disease (*J Clin Investigation* 19 788 1940) has been utilized by these authors as the basis for a viscosimetric method adaptable for the study of this trait. Employing an Ostwald viscosimeter and testing preparations of red cells washed and suspended in Tyrode's solution, an increased viscosity was observed following equilibration of the samples with nitrogen or carbon dioxide, an effect which was prevented by preliminary equilibration with carbon monoxide but not effected by alterations of pH, by

repeated washing of the erythrocytes with saline solution or by the addition of heparin oxalate or cyanide

C.P.E.

THE QUANTITATIVE DESCRIPTION OF THE FRAGILITY OF THE ERYTHROCYTE AND ITS APPLICATION TO THE STUDY OF ACHOLURIC JAUNDICE *G. Discombe* From the Department of Pathology St Bartholomew's Hospital London England *J. Path. & Bact.* 60 315-322 1948

Red cell fragility may be quantitated by counting the number of erythrocytes which survive treatment in a given solution or by measuring the hemoglobin liberated. For precise work the hemoglobinometric method using a photo-electric absorpiometer is essential. That concentration of salt which produces 50 per cent lysis is designated the mean corpuscular fragility or M.C.F. When plotted on arithmetic probability paper the points for normal subjects fall on or close to a straight line. Fragility curves from patients with classical acholuric jaundice vary considerably in form and suggest two or three groups of cells differing in M.C.F. and its standard deviation. The affected members of one family suffering from acholuric jaundice yielded straight line curves. It is suggested that this family has a genetically distinct form of the disease.

O.P.J.

EFFECT OF BAL ON COBALT INDUCED POLYCYTHEMIA IN RATS *L. O. Jacobson, E. K. Marks and E. Gatten* From the Argonne National Laboratory and the Department of Medicine University of Chicago Chicago Illinois *Proc. Soc. Exper. Biol. & Med.* 69 84-86 1948

In view of the demonstration (Fed. Proc. 5 126 1946; *J. Biol. Chem.* 165 723 1946; *Cancer Res.* 4 497 1946) that the toxic properties of cobalt are related to its effect on —SH groups, the action of BAL, a protector of —SH groups in arsenical poisoning, was studied with reference to the possible prevention of cobalt induced polycythemia in rats. No such inhibitory influence of BAL on the development of polycythemia was demonstrable when the drug was supplied three times weekly in a dose of 0.2 mm/kg concomitantly with cobaltous chloride.

C.P.E.

OXYGEN SATURATION OF STERNAL MARROW BLOOD WITH SPECIAL REFERENCE TO PATHOGENESIS OF POLYCYTHEMIA VERA *L. Berk, J. H. Burchenal, T. Wood and W. B. Castle* From the Thorndike Memorial Laboratory Second and Fourth Medical Services (Harvard) Boston City Hospital and the Department of Medicine Harvard Medical School Boston Massachusetts *Proc. Soc. Exper. Biol. & Med.* 69 316-320 1948

The authors performed gasometric measurements of the oxygen content and capacity of blood samples obtained from the sternal marrow cavity of 23 patients with polycythemia vera, 6 with secondary polycythemia, 12 with chronic anemia, and 11 with leukemia and myeloid metaplasia. Control studies were conducted on 34 individuals whose hematologic status was essentially normal. The range of percentage oxygen saturation was similar in all groups studied with the exception of patients with secondary polycythemia in whom there was a reduction of marrow oxygen saturation corresponding to the relative unsaturation of the peripheral arterial blood. Although data were obtained in some cases suggesting an increased oxygen utilization relative to the blood flow, the technique of sampling used by the authors precluded in their opinion a satisfactory demonstration of local hypoxia, to which increased red cell production in anemic states has been attributed and which may be responsible for chronic erythropoietic stimulation in patients with polycythemia vera.

C.P.E.

SOME ASPECTS OF RED CELL PRODUCTION AND DESTRUCTION *Editor R. W. Munst, E. Ponder and others* From the American Museum of Natural History New York. *Ann. New York Acad. Sc.* 48 577-704 1947

This excellent monograph comprises six articles on the architecture, production and destruction of the red cell. There are four comprehensive but concise reports on the fundamental aspects of red cell cytochemistry, endocrinology and erythropoiesis, experimental hemorrhage and iron porphyrin metabolism, and two more clinical articles on the macrocytic anemias and the hemolytic mechanisms.

S.E.

A HEMATOLOGICAL AND HISTOLOGICAL STUDY OF THE BONE MARROW AND PERIPHERAL BLOOD OF THE ADULT DOG *P E Rskers and M Coulter* From the Department of Radiation Biology The University of Rochester School of Medicine and Dentistry, Rochester New York *Am J M Sc* 216 643-655 1948

These data should provide a useful baseline for those investigators studying hematologic changes in the dog. The authors demonstrate a similar differential cell distribution in different areas of marrow although the degree of cellularity was variable

C A F

## THERAPY OF ANEMIA

OBSERVATIONS ON THE ETIOLOGIC RELATIONSHIP OF ACHYLIA GASTRICA TO PERNICIOUS ANEMIA X ACTIVITY OF VITAMIN B<sub>12</sub> AS FOOD (EXTRINSIC) FACTOR *L Berk W B Castle A D Welch R W Heimle R Anker and M. Epstein* From the Thorndike Memorial Laboratory and Harvard Medical School Boston Massachusetts and from the Departments of Medicine and Pharmacology, Western Reserve School of Medicine Cleveland Ohio New England J Med 239 911-913, 1948

The Boston investigators had previously demonstrated a heat stable food substance so-called extrinsic factor which in combination with a heat labile factor of normal gastric juice produces a hematopoietic response in patients with pernicious anemia. They report the potentiation of crude and concentrated liver extracts by gastric juice as well. This article is concerned with the action of normal gastric juice on four patients given 5 gamma of vitamin B<sub>12</sub> daily by mouth. In each a greater reticulocyte rise occurred with the simultaneous administration of gastric juice and B<sub>12</sub>. It is suggested that the extrinsic factor may be identical with or closely related to the antipernicious anemia factor of liver which itself is presumably identical with B<sub>12</sub>. Since patients with pernicious anemia have normal amounts of B<sub>12</sub> in their feces it appears that the function of normal gastric juice is to facilitate its absorption

C A F

PTEROYLGLOUTAMIC ACID AND RELATED COMPOUNDS *T H Jukes and E L R Stokstad* From the Lederle Laboratories Division American Cyanamide Co, Pearl River New York. *Physiol Rev* 28 51-106 1948

This review of folic acid knowledge delves into extensive historical data on vitamin M, vitamin B<sub>9</sub>, xanthopterin, orotic eluate factor and *Streptococcus lactis* R factor and then discusses the analysis synthesis and properties of pteroylglutamic acid. The role of the material in the nutrition of various animals (mice dogs guinea pigs pigs mink insects) is covered and the interrelationships of conjugated forms. There is a closing section the clinical uses of the drug

S E

FOLIC ACID Editor *R W Miner* From the Museum of Natural History N Y Ann New York Acad Sc 48 255-350 1948

This monograph details information on the history chemistry and pharmacology of folic acid and presents a few notes on its clinical effects in pernicious anemia and nutritional macrocytic anemia. The data cover the knowledge of the substance up to November 1948

S E

PTEROYLGLOUTAMIC ACID DEFICIENCY IN MICE HEMATOLOGIC AND HISTOLOGIC FINDINGS *D R Weir R W Heimle and A D Welch* From the Departments of Medicine and Pharmacology School of Medicine Western Reserve University and the University Hospitals of Cleveland Cleveland Ohio *Proc. Soc Exper Biol & Med* 69 211-215 1948

Maintained from the time of weaning on a pteroylglutamic acid (PGA) deficient diet and a PGA antagonist later supplemented with succinylsulfathiazole mice developed granulopenia lymphopenia, and anemia in 30-60 days. Histologic examinations of the spleen at this stage indicated practically complete cessation of normal hematopoietic activity and excessive hemosiderin deposits in that organ. Simultaneous bone marrow changes are described indicating marked hyperplasia of immature elements identified as primitive blastic cells and a depletion of more adult forms interpreted as evidence of maturation arrest. Following the parenteral administration of PGA the regimen being otherwise unaltered the characteristics of the peripheral blood spleen and marrow promptly reverted to normal. Thus whereas

the vitamin may not be required in mice for the formation of the most immature blood elements the maturation of these cells apparently depends on the presence of PGA

C.P.E.

**FAILURE OF XANTHOPTERIN TO INFLUENCE HEMATOPOIESIS AND GROWTH IN RATS** *J A Pritchard* From the Department of Pharmacology School of Medicine Western Reserve University Cleveland, Ohio *Proc. Soc. Exper Biol. & Med.* 69 221-225 1948

The effects of pteroylglutamic acid (PGA) and of xanthopterin were studied in weanling female albino rats maintained on a purified folic acid-deficient diet supplemented in one series by sulfathiazole and, in another, by succinylsulfathiazole a portion of the latter group being subjected to repeated bleedings in order to produce anemia. The majority of sulfathiazole treated rats developed anemia regarded as hemolytic in origin, accompanied by evidences of reticulocytosis leukocytosis and increased excretion of bile pigments not completely correctible by PGA or xanthopterin. Those receiving succinylsulfathiazole and in which blood loss anemia was artificially imposed, exhibited erythrocytic, leukocytic and growth responses when PGA was supplied xanthopterin proving completely inert.

C.P.E.

**A METHOD FOR STUDYING THE EFFECT OF VARIOUS SUBSTANCES UPON RED CELL MATURATION IN VITRO** *E E Hays* From the Department of Biochemistry, University of Vermont College of Medicine, Burlington Vermont *Am J. M. Sc.* 216 528-533 1948

The author describes in more detail his method of assaying hematopoietic factors in vitro. The bone marrow cells of rats are used and the number of reticulocytes counted after a period of incubation with various substances. His studies would indicate that normal rat serum, human serum, liver extracts potent in treatment of pernicious anemia,  $B_{12}$ , Tyrosine, glutathione and Bacto-yeast extract appear to have a red cell maturing effect, i.e., a high reticulocyte count in the incubated marrow. Folic acid was not active.

In vitro methods of studying hematopoiesis are needed. This method, while perhaps a rough index of alteration in the marrow cells, has the advantage of being simple and has been shown by the author in other studies to be a worthwhile assay method for potency of liver factors.

C.A.F.

**TREATMENT OF IDIOPATHIC PERNICIOUS ANEMIA** *R L Haden and D W Bortz* From the Cleveland Clinic and the Frank E. Bortz Educational Institute Cleveland, Ohio *J. A. M. A.* 138 870-873, 1948

This is a general review article which emphasizes that the necessary and sufficient therapy in pernicious anemia is refined parenteral liver extract and that all other drugs (pteroylglutamic acid, iron hydrochloric acid, vitamins, oral preparations of liver) are useless and unnecessary. There is no discussion of vitamin  $B_{12}$ .

S.E.

## LEUKOCYTES, LEUKEMIA AND LYMPHOMA

**A STUDY OF THE BLOOD OF SOME CRUSTACEA** *W C George and J Nichols* From Department of Anatomy, the University of North Carolina Chapel Hill North Carolina. *J. Morphol.* 83 425-443 1948

The blood of most crustacea contains two main classes of cells when examined in the living condition, viz. those with refractile granules or globules and those without. Careful examination with higher magnification reveals that only a few have a truly hyaline cytoplasm. In general four types of blood cells are recognizable. Lymphoid cells which are few in number, small and globular or spindle shaped. The second type are thigmotactic amoebocytes, which are semi hyaline and sometimes finely granular. These cells are the most active phagocytes of the blood and they can ingest India ink when injected into the animal. A third type consists of those cells with coarse, refractile and acidophilic granules. The fourth type of cell contains refractile granules which are intermediate in size between the fine granules usually seen in semi hyaline thigmocytes and the cells with coarse refractile granules. Type I is comparable in the mammalian lymphoblast or hemocytoblast and type II to the monocyte or free macrophage. Hematogenesis occurs in the blood channels. The clotting mechanism is powerful in some crustacea, weak in others.

O.P.J.

**MAST CELLS THEIR DISTRIBUTION IN VARIOUS HUMAN TISSUES** *J. Janis and J. R. McDonald* From the Mayo Clinic, Rochester, Minnesota Arch Path 45 622-634, 1948

Tissue mast cells have been the objects of many researches, but it took the work of Holmgren and Wilander (1937) to focus our attention on their probable physiologic role with respect to heparin production. This has stimulated investigators to apply various physical and histochemical techniques in order to ascertain the nature of the metachromatic granules in these cells. Wislocki and Dempsey (Anat Rec 96 249, 1946) studied mast cells in the human and rat and found a species difference with respect to the presence of lipoidal material. The basophilic granules were not digested by ribonuclease or hyaluronidase. Noback and Mootagna (Anat Rec. 96 279 1946) showed that alkaline phosphatase was localized in the majority of mast cell granules. The cytochrome C-cytochrome oxidase system was also present. Wislocki, Bunting and Dempsey (Am J Anat 81 1, 1947) showed that the metachromatic reaction was unaltered by hyaluronidase and that the granules did not give the Baner reaction after digestion with saliva. Mootagna and Noback (Anat Rec 100 535, 1948) have extended our knowledge by demonstrating mast cell granules contain phospholipid peroxidase and lipase. Janis and McDonald have studied the distribution of these cells in a wide variety of human tissues and have concluded that their presence in synovial membranes may explain why the hemarthrosis is often fluid in closed injuries of joints. There is a definite increase of mast cells in the synovial membrane in tuberculosis and other chronic infections. When a solution of protamine was added to fluid blood aspirated from a knee it formed a definite coagulum. This suggests that heparin may in part be responsible for the prevention of clotting in hemarthrosis.

O.P.J.

**LEUCÉMIE MYÉLOÏDE À POLYNUCLÉAIRES ET POLYGLOBULIE (MYELOID POLYNUCLEAR LEUKEMIA AND POLYCYTHEMIA)** *P. Emile Weil and S. Perles* Sang 19 442-447 1948

Polynuclear leukemia is a type of myeloid leukemia described by P. E. Weil in 1937 (Sang 5 539 1937) with the following characteristics: moderate increase of the leukocytes (average 30 000 to 50 000), 80 to 99 per cent of these leukocytes being adult polynuclears, myelocytes very scarce (2 to 3 per cent or absent), very few metamyelocytes. Bone marrow, liver, spleen show the usual features of myeloid leukemia with more than the usual ratio of adult cells (for instance, 30 per cent myelocytes, 30 per cent metamyelocytes, 30 per cent polynuclears). The evolution of the disease usually is very slow (ten years).

Since the original description Weil has seen 15 cases of such polynuclear leukemia. The red cells are usually slightly modified and some nucleated red cells can be found in the peripheral blood. In the 2 cases reported in the present communication a polycythemia between 6 and 8 millions was observed.

The authors discuss the relation between myeloid leukemia, myeloid metaplasia of the liver and spleen and polycythemia. Numerous forms of transitions are possible between these syndromes with an initial onset of polycythemia or of myeloid hyperplasia and with a more or less malignant character of this hyperplasia.

J.P.S.

**MEGAKARYOCYTIC LEUKAEMIA WITH THROMBOCYTHAEMIA** *G. Hemmeler* Clinique medicale universitaire, Lausanne (Switzerland) Schweiz Med Wchnschr 78 967-977 1948

The case described shows as an outstanding symptom a platelet count up to 3.3 millions without anemia or leukosis. In the bone marrow enormous increase of megakaryocytes with normal differential count and morphology. Clinically good general condition, no lymphomata and only slight enlargement of spleen. Treatment with urethane, arsenic and nitrogen mustard caused a decrease of thrombocythemia and splenomegaly.

The case shows a selective increase of megakaryocytopoiesis without participation of hematopoiesis or leukopoiesis.

## BOOK REVIEW

---

*The Rh Blood Groups and their Clinical Effects* By P L MOLLISON, A E MOURANT AND R R RACE Med Res Council #19 London, His Majesty's Stationery Office, 1948 Revised, reprinted November 1948 Pp 74 Price 1 shilling, 6 pence, net

This short booklet by three eminent British authorities summarizes present knowledge of the Rh-Hr factor and presents this information in an understandable manner The subject is roughly divided into three main headings, and each is discussed by the investigator most intimately concerned with that phase of the topic Dr Race describes the present concept of the genetic inheritance of the various Rh genes, their distribution in the population and the roles which the various factors of the Rh-Hr complex (C, D, E, c, d, e, ) play in incompatibility matings Dr Mollison takes up the clinical considerations of this subject He discusses in detail the ways in which iso-immunization to the Rh factor occurs, the role of sensitization in hemolytic transfusion reactions and in the causation of hemolytic disease of the newborn The topics of diagnosis, pathologic anatomy and therapy of this affection of the fetus are well handled and most of the disputed points and unsolved problems are clearly discussed Dr Mourant describes the actual mechanics of the various tests and manipulations now in use in the routine typing procedures in the diagnosis of sensitization and the establishing of the presence of hemolytic disease in the newborn

This booklet expounds concisely and quite clearly our present state of knowledge concerning this important subject

### THE CLINICAL ASSOCIATION OF MACROCYTIC ANEMIA WITH INTESTINAL STRICTURE AND ANASTOMOSIS

By D G CAMERON, M D , G M WATSON, M B , D PHIL ,  
AND L J WITTS, M D

BEFORE 1900, several Scandinavian authors had observed that intestinal stricture might be associated with an anemia resembling pernicious anemia. Faber,<sup>11</sup> who described a case of pernicious anemia in a young woman with multiple intestinal strictures, was the first to recognize the relationship between the two conditions. Other reports followed, and Meulengracht<sup>20</sup> reviewed 22 cases of macrocytic anemia associated with intestinal stricture. Little, Zervas and Trusler<sup>17</sup> described a case of anemia, with a blood picture typical of pernicious anemia, in a young man on whom a series of operations had been performed to cure a fistula, the sequel of acute appendicitis. In this case, anastomoses were present and it appears to be the first recorded in which the anemia was associated with the presence of anastomoses. This patient responded well to liver therapy and relapsed when this was discontinued. Since 1929, further cases of both stricture and anastomotic anemia have been described, though it has not always been possible to separate the two conditions. Barker and Hummel<sup>1</sup> reviewed 51 cases, 2 of their own and 49 collected from the literature. Since their publication, additional cases have been reviewed by Jensenius,<sup>16</sup> and a recent case has been reported by J. E. Richardson.<sup>22</sup>

The main features of the published cases of this anemia are analyzed in table 1. This table is based on the figures given by Barker and Hummel, but has been amended by the inclusion of cases published since their review and a further case admitted to the Radcliffe Infirmary in 1944 (R I 26019/44) which is described below. Two other cases have been reported briefly by Wintrobe<sup>3</sup> but as no details are given they have been omitted from the table. Anastomosis was the basic abnormality in 23 cases, while in 37 cases one or more strictures were present. One case had multiple diverticula. Of the anastomoses, 15 were entero-enterostomies or entero-colostomies, 2 of which had fecal fistulae in addition, and 8 were gastro-colic or high jejuno-colic fistulae. The strictures were mostly of the small intestine but 6 were in the colon. In 12 cases, the strictures were shown to be tuberculous, in 3 others regional ileitis was present or had been resected, and some cases reported as tuberculous but without definite proof, may properly belong in this category. In other cases the stricture was secondary to adhesions, and in some no cause for the stricture could be found. In some of the 8 cases where there was gastro-colic or

From the Nuffield Department of Clinical Medicine Radcliffe Infirmary Oxford England

jeuno-colic fistula the anemia may be partly attributed to an underlying lesion carcinoma or peptic ulcer. In a few cases, the intestine had been resected to a varying extent, but in no case more than 60 cm., and it is unlikely that resection was an important factor in the production of anemia, as Jensenius<sup>18</sup> has shown that much more extensive resections are necessary to produce anemia, both in man and in the experimental animal.

### CASE REPORT (R I 26019/44)

The patient was a woman of 42 whose mother was known to have pernicious anemia. In 1938 this patient first developed symptoms of subacute intestinal obstruction. After three months a laparotomy was done and adjacent loops of ileum anastomosed with relief of the abdominal symptoms. In 1939 she again became ill and was found to have a severe hyperchromic anemia with a hemoglobin value of 5.9 Gm. per cent and an erythrocyte count of 1.69 millions. The blood film showed macrocytosis, anisocytosis and poikilocytosis. Treatment at this time with an oral liver preparation was very effective.

In the summer of 1943 she was unable to obtain oral liver extract and was treated with an intramuscular preparation. In spite of intensive therapy, she began to get sore tongue and indigestion, she lost weight and the anemia recurred. She complained of abdominal discomfort and distension and of paraesthesia in the hands and feet. The stool was unformed with a bowel action usually twice a day.

She was admitted to this hospital in April 1944. There was slight clubbing of the fingers. There was extensive edema of the legs and a little glossitis. The abdomen was distended in the center by a swelling apparently composed of firm coils of bowel and there was visible and noisy peristalsis. Physical examination was otherwise negative. The blood pressure was 135/90, the urine was normal and there was no objective evidence of neurologic disease. Laboratory investigation at this time gave the following results:

<i>Blood</i>	Blood urea 22 mg. %
Hemoglobin 9.4 Gm	Plasma bilirubin 0.2 mg. %
Erythrocytes 2,630,000	Plasma phosphatase 3 units
Color index 1.2	Plasma phosphate 3.33 mg. %
Reticulocytes 1.6%	Serum calcium 7.8 mg. %
Leukocytes 3,200	Plasma cholesterol 120 mg. %
Platelets 260,000	Plasma ascorbic acid 0.2 mg. %
Hematocrit 33%	Plasma protein (total) 4.17 Gm. %
Mean cell volume 125 $\mu^3$	Plasma albumin 2.10 Gm. %
Mean cell diameter 8.24 $\mu$	Plasma globulin 1.70 Gm. %
Prothrombin time Normal	Plasma fibrinogen 0.37 Gm. %

*Sternal marrow* Smears showed an active marrow with both normoblastic and megaloblastic hemopoiesis. There were 12 per cent megaloblasts and 21 per cent normoblasts in the film.

*Fractional test meal* Free hydrochloric acid was present (this was still true in 1947).

*Barium meal* Evidence of relative small bowel obstruction with hypermotility.

*Absorption tests* Glucose and sucrose tolerance tests were within normal limits.

*Fat balance* For this test the diet contained 70 Gm. of fat daily.

	1st day	2nd day	3rd day
Total fat as per cent of dried feces	18.7	16.2	17.5
Split fat as per cent of total	91	97	99
Total fat excreted	6.36 Gm.	3.03 Gm.	6.57 Gm.

There was no occult blood in the feces.

She was treated with a low fat, high protein diet together with yeast and proteolyzed extract of liver by mouth. Plasma protein levels rose to a total of 6.1 Gm. per cent with 3.32 Gm. albumin and edema diminished. Finally, as a preliminary to operation, a transfusion of two pints of blood was given. Mr.

D C Corry operated on the patient on May 24 1944 through a right paramedian incision. The previous anastomosis was identified an inch above the ileo-caecal valve. The excluded coil of bowel, which was about two feet in length contained several strictures and the intervening musculature was greatly dilated and hypertrophied. The mesentery was thickened in a way similar to that of regional ileitis, but the bowel wall was not so rough as in regional ileitis and appeared whiter. Mr Corry resected the excluded loop and did a side-to-side anastomosis to reconstitute the bowel. Dr J R O'Brien reported as follows on the specimen:

The specimen consists of about 70 cms of small intestine, the two ends of which are honed together to form a rough circle. There are at least nine constrictions in the wall, with dilatation in between, giving a beaded effect. The largest cavity measures  $12.0 \times 7.0$  cms in diameter, and the narrowest constriction appears to be only about 0.5 cm wide. The wall is slightly thickened throughout. The average thickness is 0.4 cm while at each constriction there is considerable increase in the thickness of the wall which appears to be mainly due to muscular hypertrophy with a maximum thickness of 1.1 cms.

The mucosa appears natural except for the absence in places of rugae due presumably to the distension and there is necrosis and ulceration of the mucosa in relation to the stomata. Also in relation to these there are many polypoid outgrowths, the largest being 1.0 cm in diameter, and 0.8 cm high. This one is sessile, some are pedunculated. At one place the constriction has extended for about 4.0 cms in length while the majority of constrictions are only about 1.0 cm wide. There is considerable increase of fat in the mesentery in places particularly in relation to the stenotic areas.

Microscopically the mucosa appears to be natural but there is a very marked hypertrophy of both the muscularis mucosae and the circular and longitudinal muscles. It is the muscular hypertrophy which produces the preponderance of the increase in thickness of the wall. There is a very extensive chronic inflammatory change with a moderate amount of scarring. On top of the chronic change there is also an acute inflammatory process extending through into the muscle layer. In addition there are a large number of lymphoid aggregates scattered in the muscle layer and more particularly on the peripheral surface of the muscle in the attachment of the mesentery. There are areas of early calcification in the muscle layer. The microscopic picture is in fact disappointing, the predominant features being the acute inflammatory process with polymorphs extending into the muscle layer, the muscular hypertrophy and a background of chronic inflammation.

After operation the patient made a good recovery in all respects. Diarrhea was a little troublesome at first, but it responded to treatment with syrup of codeine and prepared chalk and by the end of two months the bowel rhythm had been re-established at one motion a day without medication. It was still necessary however for her to be careful with her diet and to avoid fresh fruit, salads and coarse vegetables. She rapidly gained weight. Parenteral liver extract was continued until October, 1944 when she became sensitized to liver and had severe reactions after the injections. At this time the blood count was red cells 5.03 million per cu mm, hemoglobin 13.2 Gm per cent, color index 0.9, white cells 7,600. The Price Jones curve which had been displaced to the right had come back to normal. The plasma proteins were 6.35 Gm per cent with 4.2 Gm albumin. It was decided to see the effect of discontinuing liver.

The patient remained well for a little less than a year. There was then a sharp relapse and in October 1945 the hemoglobin had fallen to 5.6 Gm per cent. She was therefore desensitized to liver and intramuscular treatment was resumed. All went well again until the beginning of 1947 when her father died. The patient, who is a rather emotional woman, collapsed after this and later had an illness which was called gastric influenza.

She was readmitted to hospital on April 24 1947. She had lost about 10 kilos in the last six months and there was slight clubbing of the fingers. Physical examination was otherwise negative. The stools showed no gross abnormality on microscopy or culture and no occult blood. There was moderate anemia, red cells 4,400,000 per cu mm, hemoglobin 11.6 Gm per cent, mean corpuscular volume  $99 \mu^3$ , white cells 7,100, ESR 9 mm. The plasma proteins totalled 5.1 Gm per cent with 3.0 Gm albumin. Free acid was present in the test meal in high normal concentrations. On x-ray examination there was practically no gas in the abdomen. The small bowel was much shorter than normal and the terminal loops showed a moderate degree of dilatation. There were changes in the pattern which strongly suggested an extensive recurrence of the original lesion.

Further surgery was not advised and she resumed treatment with a low residue, high protein diet.

extra vitamins and intramuscular liver extract. By May 1948 she had regained 6 kilos and was relatively free from symptoms.

### DISCUSSION

In the present patient, anemia developed after anastomosis had been performed to short-circuit a stricture due to regional ileitis, and its persistence after resection of the bypassed loop appears to be due to an extension of the disease process up the small intestine. In view of the repeated finding of free hydrochloric acid in the gastric juice, and the failure of the anemia to respond to intramuscular liver therapy until the anastomosis had been corrected, it is unlikely that the case represents the fortuitous association of Addisonian anemia with gross intestinal disease. Nevertheless, it is of interest that the patient's mother had pernicious anemia and an inherited predisposition may have been a factor. A further point worth making about this woman is that there was no obstruction to the passage of food along the small intestine, stagnation was confined to the bypassed loop.

TABLE 1—*Analysis of 61 Cases of Intestinal Stricture or Anastomosis Associated with an Anemia Resembling Pernicious Anemia*

	Present	Absent	Not recorded
Gastro intestinal symptoms	52	2	7
Glossitis	33	6	22
Neurologic disease	12	19	30
Icterus	19	19	23
Macrocytosis	49	1	11
Hyperchromia	41	11	9
Poikilocytosis	24	—	37
Leukopenia	35	7	19
Free HCl in gastric juice	24	20	17

The main features of the macrocytic anemia of intestinal stricture and anastomosis have been discussed by Barker and Hummel and by Jensenius, and they are summarized in table 1. In the 11 cases where the presence of macrocytosis has not been recorded, the blood picture has been described only as resembling that of pernicious anemia. In general, the blood picture in these anemias closely resembles that of pernicious anemia in that hyperchromia, macrocytosis and anisocytosis are prominent features. Poikilocytosis also is often prominent, in most of the cases where its presence has not been recorded, there has been no detailed description of the blood. In some cases, however, it has been noted that poikilocytosis has been slight and less than might be expected in pernicious anemia of the same degree.<sup>1 4 5 12 19</sup> These reports include 4 cases of stricture anemia and 4 of gastro-jejuno-colic fistula. In the macrocytic anemia of sprue, poikilocytosis is less prominent than in pernicious anemia. In the present series of cases, there are 9 in which steatorrhea has been demonstrated by analysis of the stool, in 4 of these, poikilocytosis was recorded as slight, in the other 5 there is no record. Nucleated red cells have been seen occasionally in peripheral blood films, and in three cases<sup>14 17 23</sup> megaloblasts have been reported.

### *The Bone Marrow*

For most of the cases, there is either no record of the bone marrow or it has simply been described as red and hyperplastic. In 8 cases, megaloblasts have been reported in the marrow. Zadek<sup>23</sup> found megaloblasts in the marrow in his two cases, Hartmann<sup>27</sup> in his, Fairley and Kilner<sup>12</sup> in their third case, Hawksley and Meulengracht<sup>15</sup> in their case, Barker and Hummel<sup>1</sup> in their 2 cases and the sternal marrow was megaloblastic in our own case. In one case, Zadek found only 1 per cent of megaloblasts in sternal marrow smears. In Barker and Hummel's first case, the sternal marrow film was said to resemble that of pernicious anemia but contained only 2.5 per cent of megaloblasts. After liver therapy, it became normal. Fairley and Kilner remark that in their case the megaloblastic transformation was far from complete. Evidently a megaloblastic transformation may be seen in the marrow similar to that of pernicious anemia, but the change may be to a lesser degree. In one case,<sup>10</sup> the marrow was aplastic, infection was present and this patient did not respond to liver therapy.

### *The Effect of Liver Therapy*

The effect of liver therapy in these cases has been reviewed by Barker and Hummel<sup>1</sup> and Jensenius.<sup>16</sup> Liver therapy was used in 27 of the 61 cases reviewed here, in 5 of these, it was without effect and in the remaining 22 a response was obtained. This response varied considerably in degree, being often less than might be expected in pernicious anemia of comparable severity. In 8 of these cases, oral administration of a liver preparation was effective, and it is important to note that in 5 cases, parenteral therapy was effective where oral administration had failed. Treatment with liver seems to have been less certain in its effect than in true pernicious anemia but it should be remembered that some of the patients who derived little benefit from liver therapy were extremely debilitated or had some complicating lesion such as carcinoma. In 4 of the 5 cases where liver therapy produced no response at all, the patients were moribund, and the fifth had active pulmonary tuberculosis from which he died after operation.

### *The Effect of Surgical Correction of the Intestinal Lesion*

The direct relation of the anemia to the intestinal lesion has been shown by the fact that, in several cases, surgical correction of the intestinal abnormality has led to cure of the anemia. In this series, operative treatment was carried out in 25 cases. The results of operation are shown in table 2. Fifteen of the cases had liver therapy in addition to surgical treatment. The mortality appears high, but in many cases the technical difficulties were considerable, and in others the presence of carcinoma as the underlying cause made success improbable. The earliest cases were undertaken before liver therapy and blood transfusion were available to improve the preoperative condition. The importance of a high protein diet to repair the hypoproteinemia and edema is also better recognized today.

The cases which survived operation will be described briefly. Sturgis and Goldhamer<sup>20</sup> (case 7) reported a case of ileo-cecal fistula with macrocytic anemia, in which an attempt was made to correct the fistula, but this was unsuccessful.

In 5 cases, operation was of no benefit or produced only a temporary remission of the anemia. Little, Zerfas and Trusler<sup>17</sup> described a case of anemia in association with two jejunal anastomoses. These were undone and 25 cm. of distended jejunum excised. Improvement followed but the anemia later recurred. Another case was noted by Bethell<sup>2</sup>, here details are lacking but resection of a stricture gave relief from a macrocytic anemia, without liver therapy, for 8 months relapse then followed the formation of fresh adhesions. The 3 remaining cases in which operation did not lead to cure of the anemia were all diagnosed as regional ileitis, and it is to be expected that the lesion would recur (Barker and Hummel,<sup>1</sup> case 1, Sturgis and Goldhamer,<sup>20</sup> case 6, and our own case). It is interesting that in the case reported by Barker and Hummel an anastomosis performed to bypass a stricture made the anemia worse.

The first case in which operation was successful was reported by Seyderhelm,<sup>23</sup> excision of a stricture curing the anemia. Another case of stricture anemia was described by Scherer.<sup>24</sup> In this instance, ileo-colostomy was performed to bypass a tuberculous stricture of the ileum, marked improvement followed during a short observation period. Butt and Watkins<sup>6</sup> described a similar case in which ileo-

TABLE 2.—*The Results of Surgical Correction*

	Number of cases
Death from operation	11
Operation technically unsuccessful	1
Failure to correct anemia	5
Cure of anemia	8
	—
Total cases	25

colostomy was performed for terminal ileitis, the operation was claimed to cure the anemia but the patient was not followed up. In these 2 cases, prolonged observation might have shown that the improvement was not maintained. Cases of gastro-jejuno-colic fistula with accompanying macrocytic anemia which was cured by surgical correction of the fistula have been reported by Fairley and Kilner<sup>1</sup> (case 1) and Bennett and Hardwick.<sup>2</sup> Christopher<sup>8</sup> described a case of macrocytic anemia in association with multiple anastomoses between the ileum and the colon, surgical correction of the intestinal lesions led to cure of the anemia, and liver therapy was not needed. W. Richardson<sup>25</sup> reported a case of macrocytic anemia in a young man in whom an entero-enterostomy had been performed as a sequel to acute appendicitis. This patient responded partly to liver therapy but jaundice remained. At a further operation it was found that about half the small intestine had been short circuited, this was corrected and the patient became completely well and needed no further liver. In a case reported by J. E. Richardson,<sup>22</sup> a high jejuno-colostomy was performed after appendicitis, and this patient developed a macrocytic anemia. Surgical correction led to complete cure.

From these results it is clear that where it has been practicable to correct the intestinal abnormality the anemia has been cured or greatly improved. In 4 of the

5 cases in which operation was unsuccessful, or produced only a temporary remission, there was an underlying abnormality which was progressive and could not be permanently eradicated by surgical measures

### *The Relation of Steatorrhea to the Macrocytic Anemia*

Macrocytic anemia may be found in other intestinal disorders, notably the steatorrheas, and as steatorrhea has been found in some of the cases reviewed here it is necessary to consider whether the macrocytic anemia of stricture or anastomosis might not arise from the presence of steatorrhea rather than directly from the intestinal lesions

In 10 of the 61 cases, the fat content of the feces has been estimated, 9 of these providing evidence of steatorrhea. In 2 other cases,<sup>1</sup> blood fat levels have been followed after ingestion of a fatty meal. In 2 cases, the stools<sup>2</sup> have been described

TABLE 3—*Steatorrhea and Macrocytic Anemia*

Bennett and Hardwick <sup>2</sup>	High jejuno-colic fistula	56	(dry)

as resembling those of sprue,<sup>9</sup> - in one case the stool was said not to be fatty,<sup>11</sup> and in another the stool is said not to have been that of sprue.<sup>25</sup> In the remaining cases, there is no specific information on the nature of the stool. In some of these cases, the stool has been noted to be offensive or pale, and steatorrhea may have been present, in most cases the presence of diarrhea, often watery, has been mentioned, and it seems likely that the majority did not have steatorrhea. Table 3 shows the cases in which laboratory evidence of steatorrhea is available.

From table 3 it is seen that 6 of the 9 cases in which there was positive evidence of steatorrhea were patients with gastro-jejuno-colic, duodeno-colic or high jejuno-colic fistula. There are 3 further cases of this description in the series, in one of these,<sup>9</sup> a diagnosis of sprue had been made originally, and in another<sup>2</sup> the stools were like those of sprue. In the third<sup>1</sup> (case 2) the blood fat curve after ingestion of a fatty meal was normal, but this method cannot be relied upon to detect abnormalities of fat absorption. It is clear that cases with gastro-colic or other high

anastomoses usually have steatorrhea, but steatorrhea has been demonstrated in only 3 of the remaining 52 cases of stricture or anastomosis, though it may have escaped observation in some of these. Our own case, in which the fecal fat output over a three-day period on a constant diet was within the normal range, demonstrates that steatorrhea is not essential to the development of macrocytic anemia in these cases. Further evidence is provided by the 2 cases, referred to above, in which the macroscopic appearance of the stool did not suggest steatorrhea. It was noted earlier that poikilocytosis, which is not a feature of sprue, was less in evidence in the cases in this series with steatorrhea, and the anemia of these cases may resemble that of sprue rather than that of pernicious anemia. Jenseni<sup>16</sup> considers that stricture anemia resembles pernicious anemia very closely, but that anastomotic anemia resembles spure. This appears to be the case only where there is a gastro-colic or high jejuno-colic fistula.

### *Pathogenesis of Stricture Anemia*

Pernicious anemia is a disease of the latter half of life which, if untreated, follows a remittent course to a fatal ending. It is characterized by a severe macrocytic and hypochromic anemia, megaloblastic change in the bone marrow, leukopenia and a therapeutic response to liver extract. In addition to abnormalities of blood formation there is evidence of increased blood destruction. The gastric secretion as a whole is reduced and achlorhydria is almost invariably present. The gastric mucosa is atrophied, this change may involve more of the alimentary tract and glossitis is common. Pathologic changes in the central nervous system are frequently present.

It is clear that most the features of pernicious anemia, given in this brief description, are present in the macrocytic anemia associated with intestinal stricture or anastomosis. Though there are some important differences the similarity is such that it is probable that the two conditions are closely related, and that the abnormal hemopoiesis present in both has a common origin. That the occurrence of macrocytic anemia with intestinal lesions does not represent the fortuitous association of the two diseases is shown by several points. The age distribution differs from that of pernicious anemia in that younger subjects are equally susceptible, free hydrochloric acid is frequently present in the gastric juice and intrinsic factor has been shown to be present in one case,<sup>36</sup> although it was absent in the only other case in which its activity was investigated.<sup>7</sup> Finally, there is the point that the anemia may be cured by surgical correction of the intestinal abnormality.

With regard to the pathogenesis of stricture anemia, Faber<sup>11</sup> originally postulated the absorption of a poison from the stagnant bowel content. Meulengracht<sup>18</sup> held the same view and considered it to support the theory of the intestinal origin of pernicious anemia, while Seyderhelm<sup>23</sup> went so far as to practice, with some success, ileostomy and lavage for pernicious anemia. After Castle's work, these views needed some modification and Barker and Hummel<sup>1</sup> considered various possibilities. It might be thought that stagnation interferes with the absorption of hemopoietic principles, but these authors found that, in general, absorption tests in these anemias were usually good. Lack of extrinsic factor in the diet or the presence of disease of the liver could not be incriminated. They concluded that the liver prin-

ciple did not act directly on the bone marrow but promoted detoxification of compounds of intestinal origin which might cause harmful changes throughout the body. It seems more probable that those compounds act by interfering with the formation, absorption or utilization of materials necessary for normal erythropoiesis.

It seems established that macrocytic anemia of intestinal origin is different from Addisonian pernicious anemia inasmuch as the secretion of hydrochloric acid and intrinsic factor by the stomach may be normal. There need be no steatorrhea. The only essential factor is stagnation, whether from intestinal stenosis or a stagnant loop. Acting on this hypothesis, we have produced blind loops in the small intestine of rats and have shown that if these loops are designed so as to be filled by peristalsis, a macrocytic anemia develops in a high proportion of the animals.<sup>31</sup> This anemia is usually fatal, but in some of the rats it has responded to treatment by injection of refined liver extract. The results of further experiments will be reported in subsequent papers.

#### SUMMARY

1. The case is reported of a woman in whom a macrocytic anemia developed after a short-circuit operation for regional ileitis. At a second operation, multiple constrictions and distentions were present in the bypassed loop.

2. The literature of macrocytic anemia associated with intestinal stenosis and anastomosis is reviewed. The anemia differs from Addisonian pernicious anemia in that the gastric secretion of hydrochloric acid and intrinsic factor may be normal. There need be no steatorrhea. It is concluded that the anemia is probably due to stagnation of intestinal contents and the absorption of toxic substances.

3. The production of blind loops in the small intestine of experimental animals offers a promising approach to the study of the macrocytic anemias.

## THE EXPERIMENTAL PRODUCTION OF MACROCYTIC ANEMIA BY OPERATIONS ON THE INTESTINAL TRACT

By D G CAMERON, B Sc, M D, G M WATSON, D Phil, M R C P, AND  
L J WITTS, M D, F R C P

THE EFFECTS of partial or total gastrectomy on the blood have been studied by many workers. The essential finding is that it is impossible to produce pernicious anemia by this means in any of the species of animals which have been used. Petri and Jensenius<sup>6</sup> have analyzed the results, and the data in table 1 are derived from their paper. They give the incidence and type of anemia after gastrectomy in experiments performed to that date. In none of the experiments has clear-cut pernicious anemia resulted, though in a few cases the blood picture has suggested that disease. Bence<sup>5</sup> reported that after two years gastrectomized pigs developed a macrocytic hyperchromic anemia with a hyperplastic bone marrow of embryonic character showing megaloblasts, his conclusions are not altogether borne out by his data, and his microphotographs do not show either a true megaloblastic reaction in the marrow or a marked macrocytosis in the peripheral blood. Geiger et al.<sup>12</sup> reported that a gastrectomized pig developed macrocytosis and hyperchromia, but they did not specify any anemia. In the rat, gastrectomy produces a microcytic hypochromic anemia.<sup>16</sup> Gastrectomized animals do not develop pernicious anemia if they become pregnant.<sup>7, 10, 18</sup> In no animal has liver been shown to be of value for the anemia of gastrectomy. In spite of these negative results, it has been shown repeatedly that in gastrectomized pigs the liver content of hemopoietic principle steadily decreases and is finally lost.<sup>4, 12, 14</sup>

The results of gastrectomy alone suggested that either the animals used have a hemopoietic system differing from that in man, or Castle's intrinsic factor is secreted in other parts of the alimentary tract as well as in the stomach. For this reason, attention was directed to the duodenum. Sharpe et al.<sup>16</sup> had shown that dried duodenum was effective in the treatment of pernicious anemia, and Meulengracht<sup>22</sup> had shown that the anti-anemic activity of the pig's stomach was greatest in preparations made from the pylorus. This, together with the histologic similarity of the Brunner glands of the duodenum and the glands of the pylorus, suggested that a pyloric gland organ was responsible for the secretion of intrinsic factor.<sup>24</sup> The distribution of the anti-anemic activity in the pig has since been shown to differ from that in man, in whom it is localized in the acid-producing portion of the stomach.<sup>11</sup>

Experiments to determine the effect of resecting the duodenum and pyloric gland organ have been carried out by several groups of workers. In some early experiments unrelated to this theory, Stasoff<sup>27</sup> had found anemia after duodenectomy while Mann and Kawamura<sup>28</sup> did not observe it. Aron and Bauer<sup>1</sup> removed the duodenum and the greater part of the pancreas from a dog and found a pro-

This investigation was in part aided by grants from the Medical Research Council and the Nuffield Foundation.

nounced hyperchromic anemia, though the animal survived only twelve days Hauswirth and Silberstein<sup>15</sup> performed pyloroduodenectomy on 8 dogs, reporting their results again after two years observation <sup>16</sup> In dogs which died a few weeks after operation there was a blood picture resembling that of pernicious anemia, with hyperchromia, anisocytosis and polychromasia, though liver therapy was without effect The remaining animals showed an anemia with fluctuating characteristics Goodman et al <sup>14</sup> excised the stomach and duodenum from pigs and found that only a mild hypochromic anemia resulted, although the liver from these animals lost its anti-pernicious anemia potency even when the duodenum

† Resection of fundus or pylorus alone

alone was resected Malmros<sup>21</sup> performed duodenectomy alone on one dog and reported a microcytic hypochromic anemia

More detailed experiments on resection of the stomach and duodenum in dogs were undertaken by Petri and his collaborators. <sup>23</sup> Three types of resection were undertaken In the first they removed the whole of the stomach and the first 2 centimeters of the duodenum, which was considered to include all the Brunner glands In the second type the pylorus and 2 centimeters of duodenum were removed, and in the third the pylorus and the whole of the duodenum All three operative procedures brought about a pellagrous and usually fatal condition accompanied by an irregular anemia of variable characteristics Macrocytosis, often transient, was seen in some animals In no case could the anemia be described as pernicious

These failures led to even more extensive resections of the gastrointestinal

tract It had been reported that both the small intestine and the large intestine possessed anti-anemic activity,<sup>2 40</sup> though these reports were later criticized<sup>10</sup> Bussabarger et al.<sup>7</sup> in addition to gastrectomy, resected 150 and 180 cm of intestine respectively from two dogs, only moderate hypochromic anemia resulted Bachrach and Fogelson,<sup>2</sup> in 7 dogs, resected the distal seven-eighths of the stomach, the duodenum, and about 30 centimeters of jejunum, which they estimated to contain the whole of the Brunner gland area, but except for a temporary post-operative anemia the animals remained healthy After a similar operation Wintrobe et al.<sup>43</sup> found a microcytic anemia The importance of the ileum was examined by Petri et al.<sup>29</sup> who, again working with dogs, resected the pylorus, 2 centimeters of duodenum, and the distal two-thirds of the small intestine Their object was to resect not only the site of formation of the intrinsic factor, but an essential part of the area to which it is reasonable to refer the interaction of the intrinsic and extrinsic factors and the absorption of the resulting hemopoietic principle These dogs developed the same signs of malnutrition which the authors had found in more limited resections An anemia was present which was macrocytic in two cases The bone marrow was normal or hypoplastic, and pernicious anemia did not develop

Some experiments have been limited to resection of the small intestine alone Miller and Rhoads<sup>45</sup> reported that excision of the greater part of the dog's ileum produces only a mild hypochromic anemia Bence<sup>5</sup> resected three meters of ileum and jejunum from a pig which subsequently became polycythemic Brown<sup>6</sup> observed the effect of excision or shortcircuiting of nearly the whole of the small intestine of the pig Excision did not lead to anemia, but when the greater part was bypassed a severe microcytic anemia was found The remaining experiments on resection of the small intestine have been reported by Petri et al.<sup>27 30</sup> and Jensenius.<sup>19</sup> These workers have studied the effect of resecting or shortcircuiting approximately two-thirds of the dog's intestine, both proximal and distal resections were tried In all cases a deficiency syndrome appeared which they have called enteroprival sprue In the majority, anemia appeared as a terminal phenomenon, it was often macrocytic but not usually hyperchromic Liver therapy was ineffective and, except in one case, the bone marrow was hypoplastic Except for the presence of macrocytosis this condition has no resemblance to pernicious anemia

With these experiments attempts to produce pernicious anemia by resection of the gastrointestinal tract would seem to have reached their practical limit In no case have they been successful and where the resection is very extensive, deficiencies other than of the hemopoietic factors must complicate the picture It is true that macrocytosis and occasionally hyperchromia, which are features of pernicious anemia, have been observed, but in the majority of cases the bone marrow has been hypoplastic, and aplastic anemia is often characterized by macrocytosis

The association of pernicious anemia with stricture and other lesions of the small intestine has been known for some time,<sup>2 9 19</sup> and there have been attempts to reproduce these conditions in experimental animals The best known are those of Seyderhelm,<sup>23 24</sup> in which strictures were formed by strips of aponeurosis fixed around the small intestine just above the cecum Seven dogs survived this operation, of these, two developed a severe macrocytic and hyperchromic anemia with

a blood picture resembling that of pernicious anemia and died in about two months. Two other dogs had a hyperchromic anemia which underwent spontaneous remission. Seyderhelm reported that megaloblasts were frequent in the peripheral blood and in the marrow. He considered the anemia to be related to the presence of an abnormal bacterial flora in the intestine. Lombardi,<sup>9</sup> in similar experiments, found a hypochromic anemia with poikilocytosis and anisocytosis but no megaloblasts. Another approach was made by Tönnis and his collaborators<sup>17-20</sup> who formed intestinal culs-de-sac 40 to 50 cm. long. These led to stagnation of the intestinal contents comparable with that seen in Seyderhelm's experiments. In fifteen dogs so treated, a moderate or severe anemia was found after two to four months, the color index was usually raised. This anemia could be relieved by the excision of the cul-de-sac, by administering intestinal antiseptics and by the parenteral injection of liver extract. Tönnis did not find megaloblasts in the blood. He reported that placing the cul-de-sac in the ileum was much less effective than in the jejunum. Recently, Renshaw et al.,<sup>21</sup> in an experimental study of gastrocolic fistula, reported that dogs in which such a fistula had been made developed a microcytic anemia in from two to six months, and in 2 of 7 animals this anemia later became macrocytic and hyperchromic. In these dogs, the greater part of the food passed into the small intestine, so that the anemia and other symptoms did not simply result from starvation, it was thought that contamination of the intestinal contents by regurgitation from the colon was responsible.

With the development of Castle's theory, experiments on the lines of those carried out by Seyderhelm and Tönnis were neglected in favor of resections of various parts of the gastrointestinal tract, despite the fact that the methods of these two authors produced an anemia more closely resembling pernicious anemia than those following resections. In view of the clinical similarity of pernicious anemia to the anemia often seen in association with human cases of stricture and of anastomosis of the small intestine, we have attempted to induce a similar anemia in rats by artificially producing strictures or anastomoses in their small intestines.<sup>22</sup>

The precise mechanism by which a macrocytic anemia may arise from the presence of intestinal stricture or anastomosis is not clear, but in the reported cases in man and the relevant experiments in animals one of two conditions has usually been present. The first is stagnation of the bowel content. This may occur above a stricture as in Seyderhelm's experiments. It may also occur in shortcircuited or blind loops of intestine, as are seen in some of the clinical reports of anastomotic anemia and in the experiments reported by Tönnis. The second condition is steatorrhea which may be found in the presence of gastrocolic or high jejunoileocolic fistulae. However, macrocytic anemia of intestinal origin is not invariably associated with steatorrhea<sup>9</sup> and consequently the experimental formation of gastrocolic fistulae seemed a less desirable approach to the problem than the formation of blind intestinal loops. We have, therefore, experimented with two different types of operation, intestinal stenosis and the formation of blind loops.

Adult albino rats of the Wistar strain, aged 4 to 6 months and of both sexes, were used for these experiments. The rats were kept on a diet which we have found to permit normal growth and reproduction.<sup>23</sup> Control rats kept on this diet for over

a year have maintained optimum blood counts. The normal values for blood counts in these rats will be published separately. The rat was chosen as the experimental animal because it is easy to handle and large numbers may be conveniently used.

### *Intestinal Stenosis*

In a small animal like the rat it seemed easier to create an intestinal stricture than to make an anastomosis. As the experiments described above and the records of comparable human cases did not suggest that anemia would be more likely to result from one procedure than the other, the formation of intestinal strictures was undertaken first. In all cases the stricture was made just above the cecum. The operative procedures used were partial occlusion of the small intestine with silk thread, bands of cellophane, or strips of aponeurosis, the injection of phenol or

FIG 1—OPERATIONS A AND B SHOWING DIRECTION OF PERISTALSIS IN LOOPS

sodium morrhuate into the intestinal wall, the insertion into the lumen of the intestine of small perspex bobbins with only a fine channel to permit passage of the intestinal contents, and partial occlusion by sewing a linear fold in the intestine. None of these methods could be relied upon to cause obstruction of a suitable degree. In a few rats, chronic obstruction and a macrocytic anemia did develop, but as the method was so unreliable, these experiments were abandoned and attempts to form intestinal anastomoses were made.

### *Formation of Blind Intestinal Loops*

It is probable that at least a third of the small intestine can be excised without serious effect on nutrition<sup>19</sup> and in our initial experiments the loop was made that length, about 12 inches. Two types of operation were used. In operation A the direction of peristalsis was such as to tend to empty the loop (fig 1-A) and in operation B peristalsis tended to fill the loop (fig 1-B).

*Operation A* The small intestine is transected at the junction of its upper and

middle thirds. The upper end of the middle third is tied off. The lower end of the upper third is brought down to the junction of the middle and lower thirds and an end-to-side anastomosis is performed. The middle third of the small intestine is thus converted into a self-emptying blind loop. Following this operation, macrocytic anemia was observed in a small porportion of animals (table 2). It was found that anemia developed only when there was some stenosis at the site of the anastomosis leading to dilatation and filling of part of the loop. The number of anemic animals obtained was small compared to the effort expended and the yield tended to decrease as our technical skill improved. This operation was accordingly abandoned in favor of operation B.

*Operation B.* In the first form of this operation the small intestine was transected at the junction of the middle and lower thirds. The lower end of the middle third

TABLE 2.—Frequency of Anemia with Self Emptying Loops

TABLE 3.—The Effect of Various Lengths of Self Filling Blind Loops

Length of Loop	Number of rats	Survived 3 wks. or more	Macrocytic anemia
12 inches	26	7	7
6 inches	12	4	1
3 inches	24	17	13

is tied off, and the upper end of the lower third of the small intestine is brought up to the junction of the upper and middle thirds, where an end-to-side anastomosis is performed. This operation is technically more difficult than operation A. The waves of peristalsis tend to break down the anastomosis, which must be much more firmly secured than in operation A. A remarkable dilatation of the blind loop occurs. With an effective self-filling loop all the animals die prematurely, some with and some without anemia. The results following this operation were encouraging and the technic was adopted as the basis for subsequent experiments to determine the optimum site and length of the blind loop (tables 3 and 4). It will be seen (table 3) that a twelve inch loop gave a very high percentage yield of anemic rats, but these animals did not survive more than four to six weeks and could not be saved by liver therapy. The results with 6 inch loops were not much better. With a 3 inch loop, however, the operative mortality was not excessive, the anemia developed more gradually, usually eight to ten weeks after operation, and the rats could generally be saved by liver treatment.

It seems clear (table 4) that it is important to place the blind loop in the middle or upper part of the small intestine. With low ileal loops the yield of anemic rats was very small. The results with jejunal and mid-intestinal loops were comparable but the latter were somewhat easier to make. The formation of a 3 inch self-filling blind loop about the middle of the small intestine has been consequently adopted as a standard technic for our subsequent experiments, and the operation will be described in detail.

#### *Technic of Standard Operation*

An intraperitoneal injection of 30 mgm of pentobarbitone in 0.1 ml of sterile distilled water is administered, and the anesthetic is completed and maintained

FIG. 2.—TRANSECTION OF SMALL INTESTINE

with ether. The hair on the abdomen is clipped short. The animal is tied on its back and the skin over the abdomen is cleansed with ether and painted with an aqueous solution of flavine. Observing aseptic technic, the abdominal cavity is opened through a 4 cm. mid-line incision. The cecum is identified and brought out. Working upwards from the cecum, approximately 40 cm. of small intestine is gently withdrawn. The upper end of the segment is clamped and divided. The free end above the point of division is securely tied off with a fine ligature (fig. 2). The free end below the point of division is retained outside while the remaining portion of the lower segment and the cecum are returned to the abdominal cavity. Working upwards from the point of division, another 7 or 8 cm. (3 inch) length of small intestine is carefully withdrawn. A loop marking the upper end of this portion is retained outside and the remainder of the segment is returned to the abdominal cavity. An opening in the loop about 2 mm. in diameter is created by making a small transverse incision through its antimesenteric surface. The open

upper end of lower segment is approximated to the opening in the loop (fig 3) and an end-to-side anastomosis is performed. Accurate apposition of the open ends is secured with four stay sutures and the anastomosis is completed by over sewing serosa to serosa (fig 4). The middle 8 cm. of the small intestine is thus converted into a self-filling blind loop. The peritoneum and muscles are closed

FIG 3 — LOOP FASHIONED OPEN ENDS IN APPPOSITION

FIG 4 — (A) — Placing the stay sutures (B) — Stay sutures completed (C) — Anastomosis complete

with a single continuous suture. The skin is closed with a continuous eversion suture. No dressing is applied.

#### *Description of the Anemia*

Macrocytic anemia has developed in a proportion of the animals subjected to each of the operations we have used and its characteristics have been the same irrespective of the type of operation. A hypochromic normocytic anemia was occasionally observed following operation A<sup>12</sup> but it has not been encountered in the later experiments.

Of the first 148 rats subjected to the standard operation, 104 (70 per cent) survived its immediate effects and of these 42 (44 per cent) developed macrocytic

anemia after an average interval of 74 postoperative days. The length of the interval ranged from 26 days to 158 days. As the later animals in this group have so far been observed for only three months, it is probable that more of them will eventually become anemic. Table 5 gives representative examples, at various levels, of the blood findings in ten consecutive anemic animals of this group. A further large number of animals is at present under observation.

Once anemia has appeared following the standard operation, it is progressive and appears to be almost invariably fatal within a month if untreated. Of 12 such untreated animals only 3 survived for more than eight days and these 3 were all dead by the thirty-fourth day. Anemic animals tend to lose weight but they do not show any external evidence of deficiency disease.

The normal hemoglobin level in our rats is about 14 Gm. per 100 ml. and anemia has not been diagnosed unless the hemoglobin level has fallen below 10 Gm. per

100 ml. Films of tail blood from the anemic animals were prepared in the usual way and stained with May-Grünwald-Giemsa. Staining of the erythrocytes varied considerably. In most fields they displayed central pallor but in a few fields staining was more uniform. Target cells were occasionally seen. Macrocytosis, anisocytosis and diffuse polychromasia were well marked in all instances. A slight degree of poikilocytosis and punctate basophilia was usually present. Nucleated red blood cells, chiefly polychromatic normoblasts, were frequently seen. No megaloblasts were observed. The mean erythrocyte diameter of each of the anemic animals in table 5 was estimated by the method of Price-Jones.<sup>20a</sup> In every case the Price-Jones curve exceeded the ideal  $+3\sigma$  curve. The chances are less than 1 in 770 that such a curve could be normal. These findings clearly demonstrated that the anemia was macrocytic. The hemoglobin readings ranged from 9.9 Gm. per 100 ml. to 2.7 Gm. per 100 ml. The erythrocyte counts ranged from 6.9 millions per cu. mm. to 2.4 millions per cu. mm. and were usually under 6 million per cu. mm. Reticulocyte counts were elevated and showed an exaggeration of the wide range found in nor-

mal animals Platelet counts and leukocyte counts were all within the normal range as were the differential white cell counts The corpuscular constants also fell within the normal range The wide variability of the corpuscular constants in the rat renders them of little value in the study of this experimental anemia

Bone-marrow smears were made from normal and anemic rats by a method which did not involve sacrifice of the animal <sup>8</sup> Smears from rats with macrocytic anemia showed normal or increased cellularity, the most striking change in distribution was an increase in the proportion of earlier red-cell precursors In smears from normal rats the predominant cells of the erythroblast series are small polychromatic normoblasts with dense or cartwheel nuclei this distribution was unaltered in rats subjected to repeated hemorrhage, but in rats with macrocytic anemia there were increased numbers of proerythroblasts and basophil erythroblasts The degree of this change varied considerably in different rats No cells were seen which corresponded exactly with the megaloblasts of human pernicious anemia, but there were some cells of the erythrocyte series which appeared abnormal in that the nucleus did not have the compact character seen in cells from normal marrow, and occasional cells had a closer resemblance to the megaloblast Marrow from anemic rats showed increased numbers of plasma cells, but there were no appreciable changes in the myeloid series

The rat is a small animal with a brisk metabolism and does not tolerate anemia well If the hemoglobin level falls much below 7 Gm per 100 ml the rat becomes torpid, loses weight and its resistance to infection becomes impaired In such circumstances, the state of ill health may become irreversible Consequently, therapeutic tests are probably best made at a level of 7-9 Gm of hemoglobin per 100 ml Preliminary observations have suggested that this experimental macrocytic anemia responds to treatment with liver extract and with pteroylglutamic acid <sup>12</sup> Experiments are now in progress to determine the effects of liver extract, pteroylglutamic acid and vitamin B<sub>12</sub> and the results will be reported separately

#### DISCUSSION

These experiments have shown that macrocytic anemia can be produced in the rat by the formation of a blind loop in the small intestine They have also confirmed two observations made by Tönnis and his collaborators in similar operations on dogs The first is that the loop must be designed so that it is filled by the action of peristalsis The second is that it must be placed in the upper or middle thirds of the small intestine The implication is that the loop must be filled with stagnant undigested intestinal contents if it is to have a pathologic effect Tönnis went on to infer that the pathologic changes are produced by the absorption of toxic substances from the loop He noted that his dogs died in a shorter time on a meat diet than on a lacto-vegetarian diet, and he observed toxic changes in the liver and the kidneys

The livers in our rats have shown no microscopic abnormality Moreover, it is characteristic that the rats appear well for two or three months after the operation and then quite suddenly become anemic and ill This suggests that the decisive event may be a change in the flora of the loop and, possibly, in the remainder

of the small intestine. This may lead to the loss of an organism which synthesizes hemopoietic material, or the predominance of an organism which uses up hemopoietic material, or the presence of an organism which produces an antagonist to hemopoiesis. Such an antagonist might interfere with the Castle reaction, as the fish tapeworm does,<sup>41</sup> or with the action of vitamin B<sub>12</sub> or folic acid. We have some evidence that life can be prolonged by treatment of the rats with Anahaemin, folic acid or vitamin B<sub>12</sub>. However, the experimental conditions are probably complex and it would be a mistake to discuss them solely in terms of anemia. A number of our rats have died without anemia and if, as we imagine, the blind loop leads to a conditioned deficiency, it is almost certainly a deficiency of more than one substance. The chief value of the blind loop preparation may be that it affords a relatively simple method of disturbing the equilibrium in the small intestine and studying the consequent changes in absorption and nutrition.

It is interesting that it is possible to produce a macrocytic anemia in animals by operations on the small intestine which lead to stagnation of the intestinal contents, whereas operations on the stomach consistently fail. In the human subject surgical procedures which involve the intestine occasionally lead to an anemia which closely resembles pernicious anemia and which responds to liver or folic acid, whereas removal of the stomach is rarely followed by pernicious anemia. Some of the features of true Addisonian anemia are still unexplained—the remissions and relapses, and the small proportion of patients with achlorhydria who develop the disease. These phenomena have been attributed to variations in the secretion of Castle's intrinsic factor, but the possibility that they are due to variations in the flora or function of the small intestine cannot be excluded.

#### SUMMARY

1. The literature concerning attempts to produce macrocytic anemia of the liver-deficiency type in animals by operations on the gastrointestinal tract has been reviewed. Operations on the stomach have failed consistently to produce such an anemia, but success has been achieved by operations on the small intestine with the creation of blind loops or intestinal stenosis.

2. The technic we have used to produce macrocytic anemia in the rat is described in detail. The essentials are that the blind loop should fill with peristalsis and that it should not be too low down in the small intestine.

3. Anemia does not usually develop until an interval of several weeks or months after the operation. It is then macrocytic in type and acute in course.

4. The anemia is probably dependent on stagnation in the blind loop and a change in the bacterial flora of the small intestine.

## THE BLOOD COUNTS OF THE ADULT ALBINO RAT

By D. G. CAMERON, B.Sc., M.D., AND G. M. WATSON, D.Phil., M.R.C.P.

IN THE course of the investigation of an experimental anemia of adult albino rats, it was necessary to determine the normal range of values for the blood counts of these animals. Normal values for rat blood counts have been reported by several authors<sup>1-9</sup> but as the published figures show discrepancies and are incomplete in some respects, our findings may be of general interest.

### METHODS

The animals used in these experiments were adult albino rats of the Wistar strain, of both sexes and aged 4 months or older. They were maintained on a synthetic diet of casein, corn starch, cod liver and arachis oils with mineral and vitamin supplements. We have found<sup>10</sup> that this diet permits normal growth and reproduction. Animals kept on it for periods of twelve months have maintained optimum blood counts.

Free flowing blood was collected from the tail after warming it in hot water and snipping a bit from the end with scissors or scalpel. The animals were not restrained and were alarmed as little as possible.

Erythrocyte and leukocyte counts were made with the usual pipets and diluting fluids but as the counts were high, it was found advisable to draw blood only to the 0.3 mark in the pipets. Hemoglobin was estimated with a previously calibrated Evelyn photoelectric colorimeter using 20 cu. mm. of blood diluted with 6 ml. of 0.4 per cent ammonia. Reticulocytes were counted by a wet film method. Blood was mixed with the diluting fluid of citrated normal saline and brilliant cresyl blue in a leukocyte pipet. A drop of the mixed blood and stain was placed on a glass slide covered and sealed with liquid paraffin. Platelets were counted in the same preparation and their absolute numbers were calculated from the erythrocyte count. For hematocrit readings a heparinized 1 mm. bore tube closed at one end and having a cup-shaped expansion at the other was used. A few drops of blood were collected in the cup, the tube was agitated to ensure mixing and then centrifuged for thirty minutes at 5000 r.p.m. The readings were made by laying the tube on squared paper. Mean corpuscular diameters were determined by Price Jones<sup>11</sup> method. An eosin-stained blood film was projected at 2000 diameters using a dry optical system and the average diameters of 500 erythrocytes were measured. The mean diameter and standard deviation were calculated for the erythrocytes of each animal.

### RESULTS

The results for male and female rats are presented separately in tables 1 and 2. Table 3 shows the range of values obtained in differential leukocyte counts.

### COMMENTS

The published figures mentioned above do not show much variation in the values found for hemoglobin content, which are in the range 13 to 15 grams per cent. The erythrocyte counts, however, vary from 6.60 million<sup>7</sup> to 9.53 million<sup>8</sup> per cu. mm. Our figures lie between these extremes. Our values for the normal leukocyte count, as well as those of Thewlis and Meyer<sup>9</sup> and Quimby et al.,<sup>12</sup> are much higher than the figures usually reported. The reason for this discrepancy is not apparent. It is probable that strain differences and variations in diet are partly responsible. Farris<sup>13</sup> reported a lymphocytosis under emotional stimulus, but

From the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford, England.

found no increase in the total leukocyte count. Recently, Quimby et al.<sup>13</sup> have shown that the leukocyte count of heart blood is much lower than that of tail blood.

TABLE 1.—*Blood Counts of the Adult Male Albino Rat*

	Number of observations	Mean	Standard error of the mean
Erythrocytes (millions per cu mm)	71	8.50	0.106
Reticulocytes (% of erythrocytes)	69	4.5	0.351
Hemoglobin (grams per 100 ml)	71	14.6	0.191
Hematocrit (% packed red cells)	69	43.5	0.642
M.C.V. (cubic microns)	69	52.2	0.707
M.C.H. (micromicrograms)	69	17.2	0.218
M.C.H.C. (per cent)	69	30.0	0.327
M.C.D. (microns)	15	5.98	0.061
Standard deviation of red cell diameters	15	0.46	0.023
Leukocytes (thousands per cu mm)	69	21.4	0.727
Platelets (thousands per cu mm)	59	673.0	40.9

TABLE 2.—*Blood Counts of the Adult Female Albino Rat*

	Number of observations	Mean	Standard error of the mean
Erythrocytes (millions per cu mm)	200	8.70	0.069
Reticulocytes (% of erythrocytes)	200	4.0	0.127
Hemoglobin (grams per 100 ml)	200	13.8	0.068
Hematocrit (% packed red cells)	76	41.8	0.409
M.C.V. (cubic microns)	76	49.0	0.600
M.C.H. (micromicrograms)	76	16.0	0.191
M.C.H.C. (per cent)	76	34.0	0.323
M.C.D. (microns)	20	6.14	0.032
Standard deviation of red cell diameters	20	0.42	0.018
Leukocytes (thousands per cu mm)	200	20.4	0.582
Platelets (thousands per cu mm.)	15	531.8	15.16

TABLE 3.—*Differential Leukocyte Counts of the Adult Albino Rat*

Cell Type	Average %	Range %
Neutrophils	15	8-24
Eosinophils	1	0-4
Lymphocytes	81	70-89
Monocytes	3	1-6

Note.—22 ♂ and 22 ♀ animals. No sex difference was noticed in the differential counts.

We have found small differences between the sexes in hemoglobin values, erythrocyte counts and hematocrit readings. The divergence is statistically significant for the hemoglobin values, but in the other cases probably does not represent a real difference due to sex.

## SUMMARY

The normal values for blood counts in the adult albino rat are presented

# OBSERVATIONS ON THE EFFECT OF AN ANIMAL PROTEIN FACTOR CONCENTRATE ON PERSONS WITH THE MACROCYTIC ANEMIA OF PERNICIOUS ANEMIA, OF NUTRITIONAL MACROCYTIC ANEMIA AND OF SPRUE, AND ON PERSONS WITH NUTRITIONAL GLOSSITIS

By TOM D SPIES M D , GUILLERMO GARCIA LOPEZ, M D , FERNANDO MILANES, M D , ROBERT E STONL, M D , RUBEN LOPEZ TOCA, M D , TOMAS ARAMBURU, M D , AND SAM KARTUS, M D

FOR THE past fifteen years, investigators have been working intensively on an illusive vitamin, or a complex of closely related factors, found in association with proteins of animal origin. For a number of years there has been evidence that soya bean meal was not adequate as the only source of protein in poultry feeds.<sup>1</sup> The hatchability of eggs produced by hens fed these diets was low, whereas this defect could be remedied by feeding meat scraps.

Later it was found that a supplement of dried cow manure was effective in increasing the egg production and the hatchability of the eggs from hens fed on such a restricted diet.<sup>2</sup> Whitson, Hammond, Titus, and Bird<sup>3</sup> concluded that the substance was not a protein or any known vitamin. Bird, Rubin, Whitson, and Haynes<sup>4</sup> aided in the search for the hatchability factor by investigating a large number of widely used foodstuffs, and Mishler, Carrick, and Hauge<sup>5</sup> found that the addition of fish solubles supplied a missing factor or factors not present in a vegetable protein ration supplemented with vitamins. Rubin, Bird, and Rothchild<sup>6</sup> demonstrated the presence of a chick growth factor in hen feces.

As these studies progressed on the new factor or factors necessary for the hatchability, growth, and viability in chicks, Ross, Phillips, and Bohstedt,<sup>7</sup> Cunha,<sup>8</sup> Spitzer and Phillips,<sup>9</sup> and Cary, Hartman, Dryden, and Likely<sup>10</sup> independently showed that proper growth, reproduction, and lactation did not occur in rats fed a diet of highly purified casein as the source of their protein and that they required an unidentified factor.

More recently, Zucker, Zucker, Babcock, and Hollister<sup>11</sup> fed rats a purified diet containing protein and all of the known essential vitamins. The female rats maintained on this diet reproduced normally and had normal lactation, but the young born of such females frequently died soon after weaning. Crude casein, fish solubles, or liver extract corrected the deficiency, and the new factor was tentatively named zoopherin. The authors pointed out that it is not the same as the fat-soluble animal protein factor of Heuser, Norris, Lucas, and Combs<sup>12</sup> and of Johnson, Carrick, and Roberts.<sup>13</sup>

Northwestern University Studies in Nutrition at the Hillman Hospital Birmingham Alabama and at the General Calixto Garcia Hospital Havana Cuba in cooperation with the University of Havana From the Department of Nutrition and Metabolism Northwestern University

This study was supported by grants from the Birmingham Citizens Committee and from Lederle Laboratories Inc

The animal protein factor concentrate was produced by micro-organisms and was supplied by Dr T H Jukes of Lederle Laboratories Inc

In another field of investigation, workers found a long-sought-for antipernicious anemia factor of liver. This substance was isolated independently by workers in the United States<sup>14</sup> and in England.<sup>15</sup> Ott, Rickes, and Wood<sup>16</sup> have reported that it possesses animal protein factor activity for the chick and concluded that this vitamin, termed B<sub>12</sub>, is identical or closely related to the animal protein factor from other sources.

The chemical nature and structure of the new vitamin B<sub>12</sub> is not fully known. Its molecular weight is between 1,350 and 1,750. It is a cobalt complex and contains phosphorus. Irrespective of whether this material should prove to be identical with one or more of the various chick growth and hatchability factors, vitamin B<sub>12</sub> is of great interest in human nutrition. There are substantial differences in nutrient needs among the species, but we must suppose that man, as well as other animals, is greatly dependent on such factors in his diet for protection. The appraisal of the worth of these particular substances to human beings is being determined by observations of therapeutic responses and by biochemical examinations of the body tissues and fluids.

It has been shown recently that concentrates from a micro-organism having animal protein factor activity were effective in inducing blood regeneration in two patients with pernicious anemia.<sup>17</sup>

The studies reported in this communication were devised to provide the answers to the following questions:

1. Could we confirm the findings of Stokstad and his associates that a concentrate produced by micro-organisms, which acts as a source of animal protein factor as measured by assay with chicks, would be effective in producing a positive hemopoietic response in persons with Addisonian pernicious anemia in relapse?

2. Would this same concentrate be effective in producing blood regeneration in persons with nutritional macrocytic anemia in relapse?

3. Would this concentrate produce a blood response in persons with the macrocytic anemia of tropical sprue in hemopoietic relapse?

4. Would it produce a remission of nutritional glossitis unassociated with macrocytic anemia?

For these studies we selected 5 cases of pernicious anemia, 4 cases of nutritional macrocytic anemia, and 3 cases of nutritional glossitis from the Nutrition Clinic of the Hillman Hospital, Birmingham, Alabama, and 3 cases of tropical sprue from the Pabellon Especial, the ward for the study of sprue, in the General Calixto Garcia Hospital, Havana, Cuba.

An important criterion in the selection of all the patients was a painful, fiery red tongue.

The following four criteria were used in the selection of all the patients with pernicious anemia, nutritional macrocytic anemia, and tropical sprue: (1) macrocytic hyperchromic anemia, (2) red blood cell count of 2,500,000 or less, (3) color index of 1.0 or more, (4) megaloblastic arrest of the sternal bone marrow.

An additional criterion for pernicious anemia was the absence of free hydrochloric acid in the gastric contents after histamine stimulation. Additional criteria for nutritional macrocytic anemia were the presence of free hydrochloric acid in

the gastric contents and diarrhea with liquid to soft, brown stools. Additional criteria for tropical sprue were the presence of free hydrochloric acid in the gastric contents, a flat glucose tolerance curve, acid steatorrhea, and loss in body weight.

All the patients except Case 1 were ambulatory and came to the hospital daily for observation and treatment. Repeated gastric analyses were made in each case. Daily studies of the peripheral blood included red and white blood cell counts, hemoglobin determinations, and reticulocyte counts made by methods previously described.<sup>18</sup> Bone marrow studies were made prior to therapy.

After the baseline determinations were completed, animal protein factor concentrate was injected in amounts ranging from a total of 5 cc. in a period of twenty-three days to 5 cc. daily for fourteen days. The following brief representative case histories illustrate the responses of one case of pernicious anemia, one case of nutritional macrocytic anemia, one case of tropical sprue, and one case of nutritional glossitis unassociated with anemia.

### CASE REPORTS

*Case 1.* M. D., a 62-year-old white woman, was admitted to the Hillman Hospital, Birmingham, Alabama, in October, 1948, complaining of weak spells and numbness and tingling of the hands, legs, and feet. Because her memory was poor, she was unable to give an accurate history. She stated that her illness began rather suddenly four years previously and was characterized by weakness and epigastric distress. At that time she remained in bed for three months but could not recall having had any specific treatment. She gained enough strength slowly to become ambulatory but she continued to feel weak. In 1947, after a period of progressive weakness, she had again become bedridden. She lost her appetite, lost weight, and developed edema of the ankles and numbness and tingling of the feet, legs, and hands. She was in bed for seven months and had numerous injections which she thought were liver extract. Following this treatment, she was able to be up for three months although the numbness of the feet, legs, and hands persisted and she felt weak. The following seven months she spent most of the time in bed. She failed to gain strength and came to the Nutrition Clinic seeking treatment. She was admitted to the Hillman Hospital, where physical examination showed a poorly developed, poorly nourished woman. The skin was pale and showed decreased elasticity. The conjunctivae were very pale and the sclerae had a slight icteric tint. The tongue showed mild glossitis. She walked with a staggering gait and watched the movement of her feet carefully. The calves were slightly tender to pressure. There was hypesthesia of the hands and forearms, hypesthesia of the fingers and hyperesthesia of the lower thighs and the legs. Touch perception in the feet was absent. There was slight blunting of position sense. The knee jerks were hyperactive. Vibratory sensation showed a great decrease at the ankles and a slight decrease at the knees and wrists. Repeated gastric analyses showed no free hydrochloric acid in the gastric juice after histamine stimulation. The blood values on admission were: red blood cells 1.73 million, white blood cells 1,900, hemoglobin 6.6 grams (42 per cent), and reticulocytes 1.6 per cent. The patient was given 5 cc. of animal protein factor concentrate intramuscularly each day for fourteen days. The reticulocytes began to rise on the fourth day of therapy and reached a peak of 16.4 per cent on the seventh day (fig. 1). Three weeks after therapy was initiated, the red blood cell count increased to 3.41 million, the white blood cell count increased to 8,750, the hemoglobin increased to 9.3 grams (60 per cent), and the reticulocytes decreased to 2.8 per cent. Eight weeks after therapy was discontinued, the red blood cell count was 3.88 million, the white blood cell count 7,750, the hemoglobin 12.4 grams (80 per cent), and the reticulocytes 1.0 per cent. The sixth day following the initiation of therapy, she had a definite improvement in appetite and consumed more food than she had previously. By the seventh day the signs of glossitis had subsided, and she stated that she felt stronger and began to spend time out of bed. At this time she seemed a little more alert mentally and she began to complain more severely of pains and paresthesia of all the extremities. Objectively, no improvement in the neurologic status could be detected except that she seemed to walk a little better and this might very well be attributed to a gain in strength rather than to any real improvement in the nervous system.

FIG 1—HEMOPOIETIC RESPONSE OF A PATIENT (M. D.) WITH PERNICIOUS ANEMIA TO ANIMAL PROTEIN FACTOR CONCENTRATE

FIG 2—HEMOPOIETIC RESPONSE OF A PATIENT (E S) WITH NUTRITIONAL MACROCYTIC ANEMIA TO ANIMAL PROTEIN FACTOR CONCENTRATE

Case 2 E S a 78 year old white man had been under observation since 1943 at which time a diagnosis of nutritional macrocytic anemia was made. Following treatment with liver extract he had had

an excellent hematologic response and the mild glossitis that was present prior to therapy disappeared. He continued to eat a very inadequate diet as he had done for several years, worked every day, and did not receive maintenance therapy. His anemia relapsed each year for the following four years and each time was accompanied by a moderately severe glossitis. Liver extract administered at the time of each relapse was followed by a good hemopoietic response and relief of the glossitis. In January, 1948, the anemia relapsed again and he had a recurrence of mild glossitis. Following the administration of 10 mg. of folic acid by mouth daily for fifty-seven days, he showed an excellent hematologic response and the glossitis gradually disappeared. He returned to his former way of life with the result that in August he had a relapse of the anemia and a recurrence of the glossitis. The glossitis disappeared and a remission of the anemia was effected following a single injection of 25 micrograms of vitamin B<sub>12</sub>. The red blood cell count rose to 3.21 million and the hemoglobin determination was 10.2 grams (67 per cent). Further vitamin B<sub>12</sub> was not available and five weeks later the blood values began to decrease and the glossitis recurred. He lost

FIG. 3.—NUTRIENTS SUPPLIED BY DIET OF PATIENT WITH MACROCYTIC ANEMIA (E S) BEFORE AND AFTER THERAPY WITH ANIMAL PROTEIN FACTOR, CONTRASTED WITH RECOMMENDED ALLOWANCES OF NUTRIENTS (recommended by Council on Foods and Nutrition National Research Council)

Dotted columns: nutrient supplied by diet of patient before treatment. Solid black columns: recommended allowance of nutrient. Diagonally shaded columns: nutrient supplied by diet of patient after treatment.

his appetite and complained of weakness. At this time he was given 2 cc. of animal protein factor concentrate intramuscularly daily for fourteen days. In figure 2, which shows his hemopoietic response, it can be seen that the reticulocytes reached a peak of 11.6 per cent on the ninth day of therapy. By the last day of therapy, the red blood cell count had increased from 2.87 million to 3.88 million, the white blood cell count from 7,700 to 9,100, and the hemoglobin from 10.2 grams (67 per cent) to 12.2 grams (79 per cent). The hematologic response was accompanied by a great improvement in the patient's appetite and food intake (fig. 3) and the glossitis disappeared four days after therapy was initiated.

**Case 3: B. B.**—a 47-year-old Cuban woman with tropical sprue was treated with folic acid at the General Calixto García Hospital, Havana, Cuba, in June 1947. She had an excellent hematologic and clinical response at this time but, following her discharge from the hospital, she resumed eating a diet similar to that she had eaten for many years. It consisted chiefly of rice, cornmeal, bread, viandas (Cuban root vegetables), coffee, and sugar. She failed to return for follow-up studies but finally appeared at the hospital in December 1948 when she had moderately severe glossitis and diarrhea. Her appetite was very poor and she was so weak that she could do little of her housework. Her blood values were: red blood cells 2.01 million, white blood cells 3,750, hemoglobin 10.6 grams (69 per cent), and reticulocytes 0.8 per cent.

She was given an injection of 1 cc of animal protein factor concentrate. Three days later she volunteered that she felt stronger and that her appetite had improved. By this time the redness of the tongue had faded considerably and the tongue was less painful. Seven days after the injection the reticulocytes reached a peak of 8.0 per cent (fig. 4). Five days later the red blood cells increased to 2.16 million, the white blood cells to 5,050, the hemoglobin to 11.0 grams (71 per cent), the diarrhea was less severe. The following day she again complained of burning of the tongue, which showed increased redness along the border and at the tip. At this time, 1 cc of animal protein factor concentrate was injected and this amount was given every other day until a total of 4 cc were given. The glossitis began to subside three days after therapy was initiated. The reticulocytes reached a peak of 9.2 per cent seven days after the initial injection of animal protein factor concentrate and by this time the diarrhea and the glossitis had disappeared.

FIG. 4.—HEMOPOIETIC RESPONSE OF PATIENT (B. B.) WITH TROPICAL SPRUE TO ANIMAL PROTEIN FACTOR CONCENTRATE

Five days later the red blood cell count was 3.00 million, the white blood cell count 7,000, the hemoglobin 12.1 grams (78 per cent) and the reticulocytes 1.2 per cent.

**Case 4.** A R. a 68 year old white woman came to the Nutrition Clinic, Birmingham, Alabama in April 1948 complaining of severe soreness of the tongue which had persisted for over a year and varied in severity from time to time. It was so sore at times that she had difficulty in eating food of any kind particularly fruit and acid foods. She had severe general stomatitis and glossitis involving all the mucous surfaces of the oral cavity including the gums. The blood values were red blood cells 4.56 million, hemoglobin 15 grams (97 per cent). Repeated gastric analyses showed no free hydrochloric acid in the gastric juice after histamine stimulation. The patient came to the Clinic frequently for observation during the next six months and throughout this time the blood values and the glossitis remained about the same. She was then given 2 cc of animal protein factor concentrate intramuscularly daily for three days and she came to the Clinic daily for observation and blood examinations. Each injection was followed by local pain which lasted for about one hour. Seventy-two hours after the first injection there was some decrease in the soreness and burning of the mouth and tongue and they were considerably less red. The

injections of animal protein factor concentrate were discontinued for four days, during which time no further improvement to the glossitis and stomatitis occurred. Then the injections were resumed in the same amounts for four days. After the second, third, and fourth doses, the patient complained of pain at the site of the injection which persisted for twenty-four hours. Examination showed areas of about 10 cm in diameter which were red, tender, and slightly swollen. The pain and tenderness in these areas increased and the injections were discontinued at the end of four days. By this time the glossitis and stomatitis had disappeared. A subsequent intradermal test with a 1 to 20 solution of the concentrate gave a strongly positive reaction which developed rapidly within the first hour. At the end of twenty-four hours an area of swelling and redness with a central area of induration and tenderness of about 10 cm in diameter remained. After forty-eight hours there was a residual area of induration and swelling at the site of the skin test.

### DISCUSSION

Since the isolation of vitamin B<sub>12</sub> about a year ago, its function has been shown to be interwoven with many chemical substances. Yet the scientific story about it really begins with the findings of Minot and Murphy, which led to the inevitable conclusion that there was an active factor existing in liver and that this factor was a specific therapeutic agent against pernicious anemia. After the isolation of vitamin B<sub>12</sub>, it was found that this antianemic substance for persons had animal protein factor activity as tested on chicks. A number of micro-organisms are capable of synthesizing vitamin B<sub>12</sub> and probably related chemical substances. For some time to come there will be much study and speculation on the chemical identities of these various animal protein factor concentrates. At the present time the limited amount of clinical, biologic, and chemical evidence available in studying animal protein factor might suggest that this substance is identical with vitamin B<sub>12</sub>. Yet a more complete evaluation is needed, and it likely will prove that once again we are dealing with a complex of chemical compounds.

### SUMMARY AND CONCLUSIONS

The intramuscular injection of animal protein factor concentrate to 5 cases of pernicious anemia in relapse, 4 cases of nutritional macrocytic anemia in relapse, and 3 cases of tropical sprue in relapse was followed by a positive hematologic response in each case as is illustrated in figures 1, 2, and 4, respectively. The parenteral administration of this material to 3 patients with nutritional glossitis unassociated with anemia was followed by the disappearance of the redness and soreness of the tongue.

## PERNICIOUS ANEMIA AND RELATED ANEMIAS TREATED WITH VITAMIN B<sub>12</sub>

By EDGAR JONES, M D , WILLIAM J DARBY, M D , PH D , AND  
JOHN R TOTTER, PH D

IN APRIL, 1948, there appeared two reports of the isolation<sup>1</sup> or concentration<sup>2</sup> from liver of red crystalline substances which were hemopoietically active in pernicious anemia West<sup>3</sup> found that the material isolated in the Research Laboratories of Merck and Company was hemopoietically active in doses of the order of a few micrograms Shorb,<sup>4</sup> in collaboration with the Merck workers, found that this material served as an essential growth factor for *Lactobacillus lactis* Dorner This led to the microbiologic designation of LLD factor For general use, however, the term vitamin B<sub>12</sub> has been adopted<sup>1</sup> The structure of this new vitamin remains unknown It has been announced<sup>5</sup> <sup>6</sup> that it contains cobalt, phosphorus, and nitrogen and that it has a molecular weight of approximately 1600 It seems likely that the active red pigment from proteolyzed liver<sup>7</sup> is identical with vitamin B<sub>12</sub> West<sup>3</sup> found that 3 patients with pernicious anemia in relapse exhibited good reticulocyte responses followed by increases in red blood cells, hemoglobin, and volume of packed red cells after treatment with single initial doses of 150 µg , 6 µg , and 3 µg of the crystalline vitamin B<sub>12</sub>, respectively

Smith<sup>2</sup> has obtained two red pigments, both highly active in pernicious anemia, from ox liver Proteolyzed liver extract was the source of the more potent materials<sup>2</sup> <sup>7</sup> Separation by partition chromatography gave preparations which were effective in pernicious anemia in 0.3 mg doses It was known that these materials were not pure Their clinical efficacy appeared to be directly proportional to the color intensity Ten batches of material had been found to have clinical activity in 26 cases of pernicious anemia It was also stated<sup>2</sup> that these pigments were effective in 3 cases of subacute combined degeneration of the spinal cord No clinical data were provided

The materials obtained by the British investigator were described as very soluble in water, but insoluble in ether or chloroform Smith concluded that they had obtained two differing forms of the liver factor effective in pernicious anemia and suggested that only this one factor is required for both the hematologic and neurologic aspects

A recent report<sup>8</sup> by the Merck group reveals that a number of sources of vitamin B<sub>12</sub> have been discovered Among these are milk powder, beef extract and culture broths of several micro-organisms Of special interest is the finding that *Streptomyces griseus*, from which streptomycin is obtained, is a source of vitamin B<sub>12</sub>

Recently Berk, Denny-Brown, Finland and Castle<sup>9</sup> have reported great neuro-

From Departments of Medicine and Biochemistry Vanderbilt University School of Medicine Nashville Tenn and Department of Biochemistry University of Arkansas School of Medicine Little Rock Ark

This work was supported in part by grants from National Vitamin Foundation Incorporated Nutrition Foundation Incorporated International Health Division of the Rockefeller Foundation

logic and hematologic improvement following the giving of vitamin B<sub>12</sub> to a patient who had experienced a hematologic relapse and developed severe neurologic damage despite therapy with pteroylglutamic (folic) acid alone. Their patient who had shown sensitivity to various liver extracts had no such reaction to vitamin B<sub>12</sub>.

Spies and co-workers,<sup>10</sup> in observations extending over a fourteen day interval, have confirmed the initial finding by West that vitamin B<sub>12</sub> has hemopoietic activity in pernicious anemia. They have also indicated that it is hemopoietically active in both sprue<sup>11, 12</sup> and nutritional macrocytic anemia.

The present report presents observations on 8 patients with pernicious anemia, one with sprue, one with nutritional macrocytic anemia, and one with anemia secondary to the absorptive defect of intestinal lipodystrophy, who have been treated with crystalline B<sub>12</sub> (Merck) for periods up to six months. The vitamin B<sub>12</sub> which

CHART 1

we used was generously supplied through the courtesy of Doctor Augustus Gibson of Merck and Company.

The following case summaries indicate the background of these patients.

#### CASE REPORTS

##### *Pernicious Anemia*

Each of these patients presented typical hematologic and marrow findings of pernicious anemia, all had histamine refractory achlorhydria, and absence of roentgenologic evidence of gastrointestinal defects except where specifically mentioned. Neurologic changes were absent except where specifically mentioned. None of the patients had diarrhea or other findings suggestive of sprue.

1. M. R. C. white female age 67 was admitted to Vanderbilt University Hospital in October 1937 with typical findings of pernicious anemia. She responded well to treatment with liver extract administered parenterally. Treatment with liver extract was continued regularly until October 1945 when it was deliberately withdrawn in order to observe the time necessary for relapse.<sup>13</sup> By May 23, 1948, relapse sufficient to permit evaluation of treatment with vitamin B<sub>12</sub> had occurred. The details of the hematologic response are shown in Chart 1. Pronounced symptomatic improvement has also been noted.

2. F. L. colored male age 45, was admitted to the Vanderbilt University Hospital in August, 1937, in an almost comatose state alternating with periods of mild delirium. His red blood cell count was 460,000 with 1.5 Gm of hemoglobin. He was treated with blood transfusions and parenteral liver extract. Two months after his admission to the hospital his red blood cell count was 3.3 million and hemoglobin 7.9 Gm. He was not seen again until two years later when he returned in relapse. He had taken liver extract injections quite irregularly and had eaten liver only occasionally. His red blood cell count was 1.75 million with 6.7 Gm of hemoglobin at this time. He was started again on therapy with liver extract which was followed by an excellent response. Liver extract injections were continued at intervals of three weeks in amounts of 30 units per injection until December 1, 1945, when it was deliberately withdrawn in order to observe the time of relapse.<sup>12</sup> By June 3, 1948, his red blood cell count had fallen to 2.3 million with 10.1 grams of hemoglobin and he was readmitted to the hospital for treatment. He was given vitamin B<sub>12</sub> with hematologic results shown in Chart 2. Following therapy with B<sub>12</sub> there has been a great increase in his sense of well being.

FL # 86765 COLORED ♂

CHART 2.

3. A. J., white male age 61 was admitted to Vanderbilt University Hospital in March 1936 with the full blown picture of pernicious anemia. Regular administration of liver extract parenterally resulted in an excellent response and had maintained satisfactory blood levels without development of neurologic symptoms. In November of 1945 liver extract was discontinued in order to permit relapse.<sup>12</sup> His blood values fell slowly until on June 12, 1948 at which time his red blood cell count was 2 million and he was admitted to the hospital for treatment. Chart 3 shows the hematologic response to vitamin B<sub>12</sub>. Coincident with the return of hematologic values to normal there was a great improvement in the sense of well-being. He has resumed his work as a carpenter.

4. O. C. white male age 50 was admitted to Thayer Hospital in December 1947 with typical blood and marrow findings of pernicious anemia. He had had a sore tongue and intermittent diarrhea during this time. He was treated with pteroylglutamic acid the hematologic values before and after treatment being shown in Chart 4. At the time of discharge from the hospital the folic acid was discontinued and injections of liver extract were advised. He discontinued all therapy and was readmitted in a hematologic relapse in July 1948. He complained of numbness and tingling of his hands and feet and there was some disturbance in his position sense and absence of vibratory sense over his ankles. The hematologic course is indicated in Chart 5. Within four weeks from the start of therapy with vitamin B<sub>12</sub> there had been a return of vibratory sense over the malleoli and complete disappearance of the paresthesias.

5. E. B. M. white male age 52 was admitted to Thayer Hospital August 13 1948. A diagnosis of pernicious anemia had been made six months earlier and he had been treated inadequately with liver

extract The hematologic findings at the time of admission and following treatment with vitamin B<sub>12</sub> are recorded in Chart 6 He gained 8 pounds in weight during his hospital stay and was greatly improved generally

CHART 3

CHART 4

6 A M., white male, age 43 entered Thayer Hospital on July 14 1948 where he was found to have typical findings of pernicious anemia For six months he had noted a burning tingling sensation associated with numbness in both hands and both feet. There was no equivocal Babinski and vibratory sense was absent over the legs below the knees A neurologic consultant concurred in the diagnosis of mild

## OC THAYER WHITE ♂

CHART 5

## ME THAYER WHITE ♂

CHART 6

combined system disease. The hematologic values before and after treatment with vitamin B<sub>12</sub> are shown in Chart 7. By three weeks after institution of therapy vibratory sensation over the lower extremities had partially returned and he no longer experienced the paresthesias. General symptomatic improvement was satisfactory.

7 W. H. M., white male, age 73, was admitted to Vanderbilt University Hospital August 3, 1948, with the findings of pernicious anemia. Glossitis and paresthesias had been particularly bothersome. Hematologic values before and after treatment with vitamin B<sub>12</sub> are shown in Chart 8. Treatment with B<sub>12</sub> has been followed by much symptomatic improvement including relief of the glossitis and paresthesias.

CHART 7

8 L. K., a white housewife, age 45, entered the Vanderbilt University Hospital in 1936 with the complete hematologic picture of pernicious anemia. Administration of parenteral liver extract was followed by rapid relief of her symptoms. She was not seen again until October 1948, when she returned in severe hematologic relapse. During the twelve year interim she had received little, if any, therapy. In addition to the hematologic findings, there was diffuse atrophy of the lingual papillae. She was given 10 µg of vitamin B<sub>12</sub> parenterally daily for twenty-two days. The hematologic response is shown in Chart 9. Coincident with this response she became much more alert mentally, the glossitis cleared, and she gained approximately 4 pounds in weight during the first month of treatment.

### Nutritional Macrocytic Anemia

E. P., a white female, age 44, was admitted to Vanderbilt University Hospital in 1944 with the complaint of nausea, vomiting, diarrhea, and weakness of two years' duration. There had been a weight loss of 64 pounds. Physical examination revealed a pale, emaciated woman with no glossitis or evidence of combined system disease. There was a normochromic anemia with 2.4 million red blood cells and 7.5 Gm of hemoglobin, and considerable variation in size and shape of the red cells. Free gastric acid was found after histamine injection. The BMR was -22 per cent of normal. Cysts of *E. histolytica* were

found in stools. Sternal bone marrow was generally hyperplastic in both the red and white cell series. No megaloblasts were noted. She was treated with liver extract transfusions of whole blood desiccated thyroid and carbasone. Upon discharge from the hospital four weeks after admission her red cell count

## WM #10730 WHITE ♂

CHART 8

## K #79682 WHITE ♀

CHART 9

was 3.5 million with 10.7 Gm of hemoglobin. There was considerable symptomatic improvement. Liver extract was discontinued but the thyroid medication was continued.

Three months later she returned to the hospital in a profound relapse. Her red cell count was 1.0 million, hemoglobin 4.0 Gm, and white cell count 1,350. The mean corpuscular volume was again within upper normal limits. Sternal bone marrow showed numerous megaloblasts.

She was given two transfusions followed by 260 units of liver extract over a period of twenty-seven days with a 31 per cent reticulocyte response. By four weeks her red cell count was 3.79 million with 11.0 Gm of hemoglobin. There was great symptomatic improvement. Liver extract was continued for six months and then deliberately discontinued. One year later she had no anemia. A cholecystectomy was performed. Thirty-two months after the last injection of liver extract there were decreased hematologic values, and bouts of diarrhea and glossitis were occurring. By September 1948, (thirty-five months after last therapy) her red cell count was 2.4 million, hemoglobin 9.5 Gm, packed red cell volume 31 per cent. She complained of increasing nocturnal diarrhea. Serum fat-soluble vitamins were: carotene, 33  $\mu$ g per cent, vitamin A, 117 international units, vitamin E, 0.56 mg per cent. The hematologic response to parenteral vitamin B<sub>12</sub> is shown in Chart 10.

Coincident with hematologic improvement there was rapid cessation of the diarrhea and general improvement.

### Sprue

P. B. This 67 year old white man entered Vanderbilt University Hospital on November 8, 1945, at which time the previously established diagnosis of sprue was confirmed and he was successfully treated with synthetic pteroylglutamate. The details of the course during that period were published as Case 3 of a previous report.<sup>14</sup>

Continued oral treatment with pteroylglutamic acid resulted in red cell values of around 3.5 million until January 1948 when a gradually increasing anemia developed. By May 1948 values had fallen to 1.6 million red cells, a packed cell volume of 23 per cent and hemoglobin of 7.6 Gm. Fat and sugar absorption had remained impaired throughout the period of observation. The hematologic decline was not accompanied by return of glossitis or diarrhea. He was then given 15 mg. of pteroylglutamic acid daily by injection with a slight reticulocyte response but with little red cell increase. He was then treated with vitamin B<sub>12</sub>. Hematologic response is shown in Chart 11. This was followed by a second reticulocyte peak slightly higher than had been observed after pteroylglutamic acid. A slight gradual erythropoiesis followed. The red cell count has now stabilized at an average level of less than 3.0 million and macrocytosis has persisted.

### Conditioned Anemia with Megaloblastic Arrest

Mrs. R. D., a 36 year old white woman entered Vanderbilt University Hospital on September 8, 1948 with the complaints of diarrhea, weight loss, and anorexia beginning ten to twelve years before. She had lost about thirty pounds during this period. Her symptoms had gradually increased until she was now

having eight to ten semiliquid stools daily. Glossitis had been noted for some months prior to admission. Tetany had occurred occasionally during the past three years. Physical examination showed emaciation,

P B #98144 WHITE ♂

CHART 11

R D #172788 WHITE ♀

CHART 12

papillary atrophy of the tongue and a positive Chvostek sign. There was no evidence of neurologic disease.

Laboratory studies revealed a red count of 3.0 million, hemoglobin of 10.5 Gm, PCV 32.0 per cent, reticulocyte count of 2.0 per cent, a histamine refractory achlorhydria, serum proteins 5.10 Gm. per 100 cc., albumin 3.75 Gm, serum calcium 7.3 mg per cent, phosphorus 3.2 mg per cent, serum vitamin C 0.24

mg per cent, serum carotene, vitamin A and tocopherol levels were respectively 36.0  $\mu$ g per cent, 122 I U per cent, and 0.54 mg per cent. An oral glucose tolerance test showed a maximum rise of 16.0 mg per cent above fasting, and a vitamin A tolerance curve following oral ingestion of 200 000 I U was as follows: fasting 107 I U, three hours 148 I U, five hours 220 I U, ten and one-half hours 162 I U. Quantitative determination of stool fat content revealed 22.5 per cent of dry weight. Marrow showed 2.0 per cent megaloblasts. Roentgenologic examination revealed coarsening of the small bowel mucosal pattern with clumping of barium and hypermotility.

FIG 1

The history and findings were thought to be compatible with either primary or secondary defective gastrointestinal absorption associated with a deficiency of hemopoietic factors. Accordingly the patient was treated with vitamin B<sub>12</sub> as indicated in Chart 12. The depicted hematologic improvement resulted accompanied by a decrease in the number of stools from six to eight per day to about three per day, a weight gain of 4 pounds within seven days associated with minimal ankle pitting and complete relief of the glossitis.

Four weeks after the initial therapy with vitamin B<sub>12</sub> she developed epigastric pain, distention and vomiting. X-ray study showed a marked narrowing of the lower ileum suggesting regional enteritis with a deficiency pattern in the remaining portion of the small intestine. Surgical exploration was carried out the small bowel being found to be remarkably swollen and thickened with a gelatinous appearance due to extensive edema. There was no inflammatory reaction in the adjacent edematous mesentery. Large

moderately indurated nodes were found at the root of the mesentery and scattered white nodules were seen throughout the mesentery. Microscopic examination of these nodes revealed a picture compatible with intestinal lipodystrophy or Whipple's disease.

### METABOLIC STUDIES

Fecal urobilinogen estimations<sup>15</sup> were made on random stool specimens from most of the patients with pernicious anemia. In all cases of pernicious anemia

\* In each case,  $\mu\text{g}/\text{Gm}$  creatinine. Concentrations of PGA of less than 0.5  $\mu\text{g}/\text{l}$  are reported as 0.0.

† In each case, units/Gm creatinine. One unit of porphyrin is defined as the extinction at 402  $\mu$  (1 cm.)  $\times$  volume.

increased values were found during relapse and these decreased upon treatment. Three illustrative cases are presented in figure 1.

Total 24-hour collections of urine were made on selected patients prior to and during the first several days of treatment. The following were determined: creatinine, total pteroylglutamic acid by a microbiologic assay, and unidentified urinary porphyrins.<sup>16</sup> These data are presented in table 1.

## DISCUSSION

Vitamin B<sub>12</sub> is the third chemically distinct substance which has been demonstrated to possess hemopoietic activity in those anemias which are characterized by megaloblastic arrest. The first group of these substances was the pteroylglutamates—the physiologic action of which has been reviewed elsewhere.<sup>17-18</sup> The second substance, thymine, was found by Spies and co-workers<sup>19</sup> to be hemopoietically active in large amounts in pernicious anemia and sprue. The preliminary nature of the reports which have appeared to date has precluded any comparative studies on the completeness of the hemopoietic response to vitamin B<sub>12</sub> or of other effects of this newly isolated substance. Furthermore, the dosages employed, ranging from 3 to 150  $\mu$ g of crystalline material, have permitted only an approximation of the minimal effective dose, for either initial response or maintenance.

Our observations on these 11 patients who have been treated with vitamin B<sub>12</sub> permit certain generalizations. Single injections of as little as 4-6  $\mu$ g to a patient with pernicious anemia may be followed by a reticulocyte response which approximates the standard response expected from liver<sup>20</sup> (Case 2). None of our patients who received less than 50 or 75  $\mu$ g of vitamin B<sub>12</sub> at a single injection during the initial phase of therapy has attained erythrocyte levels which could be termed satisfactory until additional therapy has been given. The nature of the erythrocyte responses in patients 1 and 2 indicate that the rate of utilization of the vitamin in patients with pernicious anemia approximates 10  $\mu$ g per day. This statement is based on the observation that single small injections were followed by attainment of submaximal erythrocyte levels and then decreases in red cell counts unless additional B<sub>12</sub> was administered. With increased amounts of therapy these patients then showed additional erythrocyte regeneration. In the first report<sup>1</sup> on vitamin B<sub>12</sub>, it was hypothesized that 10  $\mu$ g of the vitamin would have the approximate equivalence of 10 U.S.P. unit of injectable liver. Additional studies by West (personal communication) and Bethell and co-workers<sup>21</sup> have tended to bear out this approximation. The course of patient 8 in this series demonstrates that an excellent reticulocyte and erythrocyte response resulted from the injection of 10  $\mu$ g of B<sub>12</sub> daily. When these injections were discontinued after twenty-two days, hemo-regeneration did not continue until additional therapy was provided. Obviously, 10  $\mu$ g daily is not a quantity which will allow significant storage of the vitamin.

Table 2 presents a tabulation of the maximum reticulocyte responses in all of the patients with pernicious anemia who have been reported by others and those included in the present report. It is apparent that the maximum response is grouped about the average as expected from liver extract in a manner seemingly independent of size of dose. Reference to the charts of individual patients in this series demonstrates that attainment of the maximum reticulocyte response is not assurance that the quantity of therapeutic agent administered will support maximum hemo-regeneration. This again emphasizes the unreliability of the reticulocyte count<sup>22</sup> as a quantitative measure of activity of a substance or of the adequacy of therapy in a given patient.

Four of these patients had been treated with liver extract in a previous relapse. Upon withdrawal of liver extract they slowly relapsed.<sup>12</sup> A second remission was

then induced by vitamin B<sub>12</sub>. Table 3 shows comparative hematologic data for the two types of therapy. These observations indicate that less than maximum erythropoiesis is maintained by the parenteral administration of quantities of B<sub>12</sub> which average less than 0.75 µg daily.

Figure 2 relates the rate of erythropoiesis to dose of vitamin B<sub>12</sub> for 17 patients with pernicious anemia. This tabulation is based on 7 patients in the series here reported and 10 of the group reported by Hall and Campbell.<sup>18</sup> Only those patients are included in this tabulation whose reported count following treatment was 4.0 million or greater, and where possible, the calculation of dosage is based on the shortest interval between institution of therapy and the attainment of a sustained

level above 4.0 million. We recognize that this calculation of the average rate of increase in red cell count does not permit adjustment for the known differences in rate of erythrocyte increases associated with different initial red cell levels. Furthermore, the calculation of average daily dose of B<sub>12</sub> as made here does not recognize possible differences in rate of excretion, utilization, or degradation of the vitamin which may occur when different sized dosages are administered. Nevertheless, the data indicate that the maximum rate of erythropoiesis will require in most cases more than 1.0 microgram of vitamin B<sub>12</sub> per day. The one patient from our series which exhibits a maximum rate of erythropoiesis on 1.0 µg of B<sub>12</sub> received daily injections and may have, thereby, utilized the material more efficiently. Hemopoiesis seems to be more consistently rapid in those patients receiving 2.5 micrograms or more of B<sub>12</sub> per day. These several considerations lead

us to make the tentative suggestion that a reasonable dosage schedule for vitamin B<sub>12</sub> in the treatment of pernicious anemia should provide approximately 30 micrograms of the vitamin daily during the first six weeks or so, and that a maintenance dose of 10 microgram per day thereafter does not appear unreasonable

TABLE 3—Comparison of the Response to Adequate Therapy with Liver Extract with the Response to Vitamin B<sub>12</sub> in a Subsequent Relapse

In addition to these hematologic observations, we have noted the expected disappearance of megaloblasts from the marrow of patients treated with vitamin B<sub>12</sub> and the appearance of numerous normoblasts in the marrow during the early phase of remission. The hemopoietic response to vitamin B<sub>12</sub> has been accompanied by a decrease in the fecal urobilinogen (fig. 1). It is known that liver extract promotes a similar reduction in fecal urobilinogen in the patient with pernicious anemia. We have observed like decreases in fecal urobilinogen in patients treated with folic acid. The exact interpretation of this observation, however, is not clear. In the

past such findings have been interpreted as indicating that the breakdown of red cells has decreased and, indeed, such an interpretation is consistent with new evidence<sup>44</sup> that pernicious anemia is a true hemolytic syndrome. It may be, therefore, that vitamin B<sub>12</sub> and PGA decrease the fecal urobilinogen of patients with pernicious anemia by promoting the formation of a more nearly normal erythrocyte. On the other hand, these findings might also reflect a decrease in urobilinogen formation due to a postulated effect of vitamin B<sub>12</sub> on some step in pigment metabolism quite apart from the breakdown of hemoglobin. London, Shemin, and Rittenberg<sup>45</sup> have demonstrated that a significant portion of the normal stercobilin production must come from sources other than hemoglobin. It may be, therefore,

FIG. 2.

that the site of action of vitamin B<sub>12</sub>, PGA, etc., in pigment metabolism is on this step rather than in the production of a normal cell. Again, it may be that the different hemopoietic agents do not act at the same point. Studies of this possibility may aid in elucidating the paradox of two chemically distinct factors exhibiting like metabolic effects in the patient with pernicious anemia. Investigations of these possibilities are under way.

Vitamin B<sub>12</sub> administration had no effect on the urinary excretion of PGA in the six cases of pernicious anemia and the one case of sprue investigated (Table 1). This does not rule out a possible metabolic inter-effect of B<sub>12</sub> on pteroylglutamates, but it does suggest that administration of effective doses of B<sub>12</sub> does not result in a great release of PGA. It is to be noted that the patient with sprue had been saturated with PGA prior to the giving of B<sub>12</sub>. Even under this circumstance there was no increase in urinary loss of PGA attributable to the B<sub>12</sub>.

The urinary porphyrin values in arbitrary units are also included in table 1. It is obvious that no recurring pattern of porphyrin excretion in 24-hour specimens followed B<sub>12</sub> therapy. Since separate 2-hour collections were not made, it is impossible to state whether an increased excretion occurred at 2 to 4 hours after therapy such as has been noted following PGA.<sup>15</sup>

Our two patients with mild neurologic involvement improved while receiving vitamin B<sub>12</sub>. This observation confirms the reported experience of both Ungley (as quoted by Smith<sup>2</sup>) and Castle and co-workers<sup>9</sup> and indicates that vitamin B<sub>12</sub> is more nearly complete replacement for patients with pernicious anemia than is either thymine or folic acid.

The response of the single patient we have observed with nutritional macrocytic anemia was equally good to vitamin B<sub>12</sub> as to liver extract. In the patient with sprue, on the other hand, the evidence is not so clear-cut. This patient had initially exhibited a rapid response to synthetic folic acid, and although he had attained submaximal erythrocyte levels, these levels were equally as high as he had previously reached during a period of intensive treatment with liver extract. A hematologic relapse occurred while he was receiving presumably adequate therapy with PGA. The relative resistance of this patient to PGA was further attested by the finding that he showed very little response to administration of 15 mg of pteroylglutamate per day parenterally. Upon the subsequent administration of vitamin B<sub>12</sub>, the patient exhibited a definite reticulocytosis and a gradual increase in red cells, hemoglobin and packed cell volume. Over a period of twenty seven weeks, very large quantities of B<sub>12</sub> have been administered and, as yet, the patient has not attained as high erythrocyte count as he had previously reached on liver extract or on folic acid. A thorough study has revealed no complicating disease which would account for this incomplete response. These observations are compatible with the interpretation that this patient has become deficient in some additional hemopoietic factor during the two and one-half to three years of therapy with folic acid alone.

The patient with anemia associated with intestinal lipodystrophy is believed to represent a deficiency of the hemopoietic factor conditioned by the gastrointestinal defect. The absorptive defect was unaltered by the vitamin B<sub>12</sub> as was to be expected when the true nature of the defect was revealed. This patient and two similar ones which we have observed in the past three years lead us to think that much of the idiopathic steatorrhea, often mistakenly classified as sprue or nontropical sprue, and which is stubbornly resistant to treatment with liver or pteroylglutamates may be primary gastrointestinal disease with conditioned anemias.

#### SUMMARY

Eleven cases treated with vitamin B<sub>12</sub> have been presented. Eight patients with pernicious anemia in relapse responded hematologically. Two patients with mild neurologic involvement were relieved by therapy with B<sub>12</sub> alone.

Consideration of the quantities of the crystalline vitamin required to promote maximal erythropoiesis in pernicious anemia indicates that less than about 0.75

$\mu\text{g}$  daily in doses at intervals of several days will not suffice to establish and maintain blood values as high as does adequate treatment with liver extract. Parenteral daily doses of  $10 \mu\text{g}$  promoted good erythropoiesis in one patient, although it appears that the maximum rate of hemopoiesis may require the initial average daily dose of approximately  $30 \mu\text{g}$ .

The reticulocyte count is an unreliable quantitative criterion of activity or adequacy of therapy.

It is suggested that hemopoietic factors in addition to PGA and  $\text{B}_{12}$  may be required by some patients to obtain maximal erythrocyte levels.

Vitamin  $\text{B}_{12}$ , as well as PGA, effects a reduction in the fecal urobilinogen output of patients with pernicious anemia. The significance of this finding is discussed.

No change in urinary excretion of pteroylglutamate or of porphyrin was detected in patients treated with vitamin  $\text{B}_{12}$ .

# COMPARISON OF VITAMIN B<sub>12</sub> FROM LIVER AND FROM *STREPTOMYCES GRISEUS* IN THE TREATMENT OF PERNICIOUS ANEMIA

By LOWELL A. ERF, M.D., AND BRUCE WIMER, M.D.

THIS communication describes the results of treatment of three cases of pernicious anemia in relapse, one with vitamin B<sub>12</sub>\* derived from liver and two with vitamin B<sub>12</sub>† derived from *Streptomyces griseus*, the latter preparation has been used also in 5 cases of pernicious anemia in remission.

Vitamin B<sub>12</sub>, a crystalline material isolated from liver, has been shown to be a potent anti-pernicious anemia substance. In 17 reported cases of pernicious anemia in relapse (table 1), all have shown definite hematologic responses when vitamin B<sub>12</sub> was administered in microgram doses. There was a prompt increase in circulating reticulocytes in those cases where the initial erythrocyte count was below 2,000,000. In all 17 cases there was a rise in hemoglobin levels and the erythrocyte counts, the levels usually approached normal in six to eight weeks if the total dosage was adequate. The bone marrow regenerated promptly (48-72 hours) from a rubriblastic<sup>7</sup> (megaloblastic) hyperplasia to a rubricytic (normoblastic) hyperplasia.<sup>6</sup>

The response of neurologic complications was followed in 13 of the 17 cases of pernicious anemia.<sup>1, 4, 12</sup> The initial observations indicate that vitamin B<sub>12</sub> is effective, as is liver extract, in producing at least a partial remission of the neurologic manifestations. There was virtually a complete remission in one case which was treated shortly after the onset of neurologic complaints.<sup>1</sup> In the other cases paresthesia, ataxia and Romberg's phenomenon responded reasonably well while the loss of vibration sense and position sense were relatively more resistant to treatment.<sup>4</sup>

A vitamin B<sub>12</sub>-like substance has recently been isolated from cultures of *Streptomyces griseus*.<sup>8</sup> The crystals isolated from this new source have physical and chemical properties very similar to crystalline vitamin B<sub>12</sub> from liver and the two substances have almost the same growth promoting potency for *Lactobacillus lactis* Dorner, and West<sup>8</sup> has found that the clinical response in pernicious anemia to the new substance parallels that produced by crystalline vitamin B<sub>12</sub>.<sup>16</sup>

## CASE REPORTS

### *Vitamin B<sub>12</sub> from Liver: The Treatment of One Case of Pernicious Anemia in Relapse*

**History.** Mrs. A. O. B., a 64 year old white woman of Irish descent was admitted to Jefferson Hospital September 24, 1948 because of progressive weakness starting July, 1948. Anorexia became a major

From the Charlotte Drake Cardeza Foundation and Department of Medicine, Jefferson Medical College and Hospital, Philadelphia, Pa.

\* Vitamin B<sub>12</sub> derived from liver supplied through the courtesy of Dr. A. Gibson, Merck and Co. Rahway, New Jersey.

† Vitamin B<sub>12</sub> derived from *Streptomyces griseus* supplied through the courtesy of Dr. Charles Mann, E. R. Squibb & Sons, New York City.

complaint. Her eyes tired easily during the week before admission and two days previous to admission tinnitus would occur when she lay down. She also noted numbness and tingling of the fingers. One day prior to admission she found that she had to use her arms to support herself when she stood up. Her weakness bordered on collapse and she was sent to the hospital.

**Past History.** The patient's general health had been good until 1932, when she was found to have hypertension. She had epistaxis at that time and again on two subsequent occasions. In July 1946 and in April 1948 she had two severe vascular accidents with hemiplegia. Recovery was good but not complete in that the patient still complained of uneven gait and weakness of the right upper extremity at the time of admission. She had lost 23 pounds of weight during 1947 and 1948.

**Physical Examination.** The patient was a white haired blue-eyed woman of short medium build. There was marked pallor of the skin, conjunctivae and mucous membranes. An herpetic lesion was seen on the left upper lip. The lingual papillae were atrophic. The blood pressure was 120/70. The neurologist reported the following findings: Grade II arteriosclerosis of the retinal vessels; slight weakness of the right upper and lower extremities as compared with the left; reflexes hyperactive bilaterally; plantar reflex weakly extensor on the right; vibration sense of the legs and ankles slightly decreased; impairment of position sense of both large toes; gait unsteady; swaying in performance of Romberg's

TABLE 1—Treatment of Pernicious Anemia with Vitamin B<sub>12</sub> from Liver

First Author Only	Number of Cases of Pernicious Anemia	Dosage of Vitamin B <sub>12</sub>
West <sup>12</sup>	3	Single doses of 3, 6, and 150 $\mu$ g respectively
Spies <sup>11</sup>	2	Single doses of 6 $\mu$ g and 15 $\mu$ g
Berk <sup>1</sup>	1	5 $\mu$ g daily for 8 days and 5 $\mu$ g 3 times weekly from 16th to 60th day
Hall <sup>6</sup>	11	Total of 40 to 325 $\mu$ g during in intervals of 30 to 50 days
	—	
	17	

test and single foot standing. The patient was responsive but there was some confusion and memory impairment. The neurologist's impression was that there were signs of combined system disease attributed primarily to arteriosclerosis and secondarily to pernicious anemia.

**Laboratory Findings.** Hemoglobin 35.6 per cent (5.4 Gm). Erythrocytes 1,580,000. Leukocytes 4,400. Platelets 72,000. Differential: segmented polys, 77 per cent; medium and small lymphocytes 17 per cent; monocytes 6 per cent. Smear of peripheral blood—typical macrocytic anemia with anisocytosis and poikilocytosis. Hematocrit, 17 per cent. Mean corpuscular volume, 107. Bone marrow rubriblastic (megaloblastic) (see fig. 1). Urine concentration test, 1:006, 1:010, 1:010. Gastric analysis achlorhydria (with histamine). Gastroscopic examination: severe degree of atrophy of the stomach mucosa. Fluoroscopic examination of the chest: healed tuberculous lesion of the left apex. Heart had an aortic configuration and was hypertrophied 10 to 15 per cent above normal. Electrocardiogram: left axis deviation. Intravenous pyelogram: ptosis of the kidneys bilaterally, in the upright position.

**Diagnosis.** (1) Pernicious anemia in relapse. (2) Combined system disease secondary to arteriosclerosis and pernicious anemia. (3) Cerebral arteriosclerosis. (4) Arteriosclerotic cardiovascular renal disease.

**Treatment.** The patient was given 25  $\mu$ g of vitamin B<sub>12</sub> from liver on October 4 and a second dose of 25  $\mu$ g on October 5, 1948.

**Course.** The hematologic changes are shown in table 2. The reticulocytes rose the second day after injection and reached a maximum of 33.8 per cent on the sixth day. The ascent of the erythrocyte count and hemoglobin level started at the end of the first week and a peak of 3,900,000 (erythrocyte count) and 83 per cent or 12.8 Gm (hemoglobin) was reached December 29, 1948, eighty-six days after treatment was instituted. The counts then started to decline, reaching 3,200,000 (erythrocyte count) and

68.5 percent or 10.5 Gm (hemoglobin) on January 16, 1949, the 114th day. The bone marrow had become rubricytic by the sixth day after injections of vitamin B<sub>12</sub> (fig. 2).

Improvement in the patient's strength and appetite started within three or four days after the injections. Mentally she became more alert. Paresthesias did not recur and the patient was able to walk without assistance although her gait was somewhat cautious and onsteady. Following her discharge from the hospital October 18, 1948, the patient's symptomatic improvement paralleled the rise in blood count. However, when the erythrocyte count exceeded 3,000,000 the elevation of blood pressure returned, varying between 160/90 and 180/100. A re-evaluation by the neurologist January 24, 1949, reported the same findings as previously except for the presence of normal position sense. At this time it was thought that positive neurologic findings were due to the previous strokes. Even at the time that the blood levels started to fall (January 24, 1949) the patient stated she felt well.

FIG. 1.—RUBRICYTIC HYPERPLASIA

Sternal marrow obtained from Mrs. A. O. B. on 9-31-48 before the administration of vitamin B<sub>12</sub> from liver.

### *Vitamin B<sub>12</sub> from Streptomyces griseus: The Treatment of Two Cases of Pernicious Anemia in Relapse*

**Case I History.** Mr. A. C., a 67-year-old Italian laborer, had been treated for pernicious anemia in the Hematology Out Patient Department since 1939. The anemia was adequately controlled with liver extract, but in September 1948 he stopped coming to clinic because he thought he was cured.

In November 1948 the patient noticed the onset of progressive weakness and in a month's time he was too incapacitated to continue work. He began to experience intermittent nausea and vomiting and epigastric distress after eating. His appetite declined and finally became so poor that he ate virtually nothing during the three days before he was admitted to the Jefferson Hospital January 7, 1949.

**Physical Examination.** The patient was a well-nourished elderly Italian with pronounced pallor of the skin and mucous membranes. Sclerae and buccal mucosae were faintly icteric. The tongue was pale, smooth and glistening. The heart was enlarged and the rhythm was irregular because of frequent extrasystoles. A systolic murmur was heard over the entire precordium, loudest over the aortic area. The liver was enlarged 3-4 cm. below the costal margin on deep inspiration and the tip of the spleen could be felt. The blood pressure was 120/80. The neurologist could find no abnormal neurologic changes.

*Laboratory Findings* Hemoglobin 40 per cent (6.16 Gm) Erythrocytes 1,610,000 Reticulocytes 1.1 Leukocytes 4,450 Differential segmented polys 57 per cent medium and small lymphocytes, 38 per cent monocytes 8 per cent normoblasts, 1 per cent smear of peripheral blood revealed macrocytosis anisocytosis, poikilocytosis and rubricytosis Bone marrow rubriclastic and prnrubricytic (see fig 3)

FIG. 4—RUBRICYTIC HYPERPLASIA

Sternal marrow obtained on 1-13-49 from Mr. A. C., six days after the administration of 32  $\mu$ g of vitamin B<sub>12</sub> from *Streptomyces griseus*.

**Case II History.** Mrs. K. R., a 47-year-old secretary of Irish descent, was first seen January 12, 1949 because of pallor, weakness and staggering. The patient noticed onset of progressive weakness early in November 1948. Two weeks later she found it necessary to stop work because of exhaustion. Although she was able to perform minimal household tasks her clinical course was downhill. At the end of Decem-

ber she developed staggering and her appetite began to wane. In January, her legs became increasingly edematous. She attributed these symptoms to a rundown condition but the exhaustion and pallor in her lips finally became so striking she had to consult a physician.

**Past History.** About ten years previously the patient had an episode of weakness which necessitated six months period of rest at home. Her physician advised a diet high in liver, meat and vegetables. She was given a few injections the nature of which she did not know. The symptoms gradually subsided and although she never felt well she was able to work the succeeding nine years until December 1947 when weakness again became incapacitating. She was placed on the same diet and given an oral tonic. Symptoms subsided to the extent that she was able to start work in April 1948 and continue until the onset of the present episode in November 1948.

**Physical Examination.** The patient was a white haired, blue-eyed white woman with extreme pallor. She had to be supported by two people when she walked because of weakness and staggering gait. There was pronounced mental dullness, confusion and memory loss. Her tongue was pale with smooth glistening edges. There were scattered areas of vitiligo and brownish pigmentation of the skin over the shoulders.

and at the neckline. The heart sounds were rapid and weak and there were fine rales at both bases. The skin was dry and waxy and there was pronounced edema of the hands, legs and ankles. Neurologic findings included the following: Pronounced weakness of hand grip (without atrophy), hyperactive biceps, triceps and quadriceps reflexes, a positive Hoffmann's sign more pronounced on the left, hyperesthesia about the ankles, impaired large toe position sense, positive Babinski's sign bilaterally, absence of vibration sense up to the iliac crests, where it was impaired, pronounced ataxia and positive Romberg's sign.

**Laboratory Findings.** Hemoglobin 22 per cent (3.25 Gm). Erythrocytes, 1,020,000. Reticulocytes, 1.6 per cent. Leukocytes, 3,500. Differential polys 45 per cent, eosin 3 per cent, myelocytes 1 per cent, lymphocytes 51 per cent. Normoblasts, 17 per 100 WBC, smear of peripheral blood was characteristic of pernicious anemia showing macrocytosis, anisocytosis, poikilocytosis and rubricytosis. Bone marrow rubriblastic (fig 5).

**Diagnosis.** (1) Pernicious anemia in relapse. (2) Subacute combined degeneration.

**Treatment.** An injection of 32  $\mu$ g of vitamin B<sub>12</sub> from *Streptomyces griseus* was given on January 12, 1949. The dose was repeated January 21, 1949 because of the severity of neurologic symptoms.

**Course.** The hemoglobin and reticulocyte levels are shown on table 4. There was a prompt rise of reticulocytes starting 48-72 hours after the first injection and reaching a maximum about the fifth day. The bone marrow 41 hours later showed maturation of rubriblasts toward prorubricytes (fig 6). The erythrocyte count started to rise significantly the fifth day and reached 1,940,000 by the sixteenth day.

FIG 5—RUBRIBLASTIC HYPERPLASIA

Sternal marrow obtained on 1-12-49 from Mrs. K. R. before the administration of vitamin B<sub>12</sub> from *Streptomyces griseus*

FIG 6—PRORUBRICYTIC AND RUBRICYTIC HYPERPLASIA

Sternal marrow obtained on 1-14-49 from Mrs. K. R., 41 hours after the administration of 32 µg of vitamin B<sub>12</sub> from *Streptomyces griseus*

Weakness and anorexia started to disappear within four days. By the sixth day the patient was able to resume physical activity without help. Increased color became evident about the seventh day. The edema of the hands and feet gradually subsided. Mentally, the patient was still retarded on the fifth day but was

able to give fragments of the past history previously denied. By the ninth day she was almost normally responsive and was able to give particulars of her past history. The neurologic improvement is shown in table 5. Neurologically there was steady improvement of ataxia and performance of Romberg's test the first week. On the sixteenth day the gait was only slightly ataxic. There was a slower improvement in the other neurologic findings.

### Vitamin B<sub>12</sub> from *Streptomyces Griseus* The Treatment of Five Cases of Pernicious Anemia in Remission

A single dose of 32 µg of vitamin B<sub>12</sub> from *Streptomyces griseus* was given intramuscularly to each of five patients with pernicious anemia who had been receiving liver extract regularly for periods varying from six months to ten years. All but one of these patients had associated diseases: arteriosclerosis and cystitis (case 3), diabetes mellitus (case 4), hypothyroidism (case 5), and latent lues (case 7). Four patients (cases 3, 5, 6, 7) appeared rather resistant to treatment with liver extract in that their erythrocyte levels remained below optimum or they had complained frequently of weakness and/or poor appetite.

The hematologic responses following injection of vitamin B<sub>12</sub> from *Streptomyces griseus* are shown in table 6. There was a slight reticulocyte increase (1.8–4.9 per cent) in only one patient (case 7) whose initial erythrocyte count was 3,000,000. In one patient (case 6) there was a significant rise in erythrocyte count.

The clinical response to treatment is indicated in table 7. Four of the five reported subjective improvement (cases 3, 5, 6, 7) mainly better appetite, increased strength and more endurance. In two instances there was significant weight gain (case 3 7½ lbs, case 6 13 lbs).

### DISCUSSION

Shorb<sup>10</sup> found by microbiologic assay that vitamin B<sub>12</sub> has 11,000 times more growth promoting potency for *Lactobacillus lactis* Dorner than a standard concentrated liver extract and estimated by this method that 1 µg of vitamin B<sub>12</sub> is

TABLE 7—Clinical Response of Five Patients with Pernicious Anemia in Remission Treated with Vitamin B<sub>12</sub> from *Streptomyces griseus*

approximately equivalent to 1 U S P unit of liver extract. Clinical studies, on cases of pernicious anemia, also imply that this ratio is approximately the same for the anti-pernicious anemia activity of the two substances. Thus, for example, in the first case reported in this paper, the dosage of 50 µg of vitamin B<sub>12</sub> produced a rise of circulating erythrocytes from 1,600,000 to 3,900,000 per cu mm. From previous computations<sup>13</sup> a similar rise of 2,300,000 erythrocytes per cu mm should have been obtained by the daily administration of 1 to 2 units of liver extract for a four and one-half week period (total dosage between 32 and 64 units). In general it appears that a satisfactory remission can be produced by a dosage of 50-100 µg of vitamin B<sub>12</sub>, whereas the number of U S P units of liver extract necessary to pro-

duce a remission is about 56-102.<sup>13</sup> The relative accuracy of this correlation between the clinical response to vitamin B<sub>12</sub> and its LLD potency emphasizes the importance of the microbiologic assay method.

In treating the first case (Mrs. A. O. B.) a dose of 50 µg of vitamin B<sub>1</sub> from liver was given during the first two days and further treatment was withheld during a 114 day period of observation to determine the type and duration of response to this method of administration. The hematologic remission was probably suboptimal because the erythrocyte count did not reach the desired level. There was, however, complete remission of all symptoms attributable to pernicious anemia. The rise in red cell levels lasted about 86 days, at the end of which time the erythrocyte count and hemoglobin levels started to descend. A suboptimal response following a single initial dose would depend upon either an inadequate dose or an inability of the patient to store amounts in excess of the immediate need at the time of injection.

The hematologic improvement of 2 cases of pernicious anemia in relapse (Mr. A. C. and Mrs. K. R.) treated with vitamin B<sub>12</sub> derived from *Streptomyces griseus* is similar to that obtained by others who gave vitamin B<sub>12</sub> from liver and used dosages of the same magnitude. These two patients had an early reticulocyte rise which was followed by a steady elevation of the erythrocyte level. The clinical symptoms of weakness, exhaustion, and anorexia disappeared rapidly and the neurologic improvement in one case (Mrs. K. R.) was definite from a functional standpoint although the tendency for some of the physical signs, such as pathologic reflexes, loss of vibration and position sense, to disappear was slow during a two week period of observation. These changes are not unlike the results obtained in the treatment of similar cases with vitamin B<sub>12</sub>.<sup>1-4</sup> These initial results make it appear that from the clinical standpoint both vitamin B<sub>12</sub> from liver and vitamin B<sub>12</sub> from *Streptomyces griseus* are either closely similar or identical in their physiologic action.

The administration of vitamin B<sub>12</sub> from *Streptomyces griseus* to 5 patients with pernicious anemia in remission resulted in minor subjective and objective improvements in 4 of the 5 cases. In one patient who had been receiving 15 U.S.P. units liver extract every week, there was a significant rise in the erythrocyte count (3,300,000 to 4,000,000 cu. mm.) following the injection of vitamin B<sub>12</sub> from *Streptomyces griseus*. It is probable that an equivalent dosage (i.e., about 32 units) of liver extract would have produced a similar result.

All evidence available at present indicates that vitamin B<sub>12</sub> is the active anti-pernicious anemia factor in liver extract. Its reaction in cases of pernicious anemia is in every way comparable to that of liver extract, differing only in that it produces an earlier reticulocyte rise and a reticulocyte peak on the fifth day compared to the seventh day with liver extract. Vitamin B<sub>12</sub> has the advantage that it is nonirritating when injected intramuscularly. Berk et al.<sup>1</sup> reported a case allergic to both beef and pork liver extract but who developed no reaction when vitamin B<sub>12</sub> was administered. This new substance makes possible the administration of large doses of the specific factor in concentrated form which may prove to be a distinct advantage in the treatment of patients who are resistant to treatment with liver extract or in patients with severe neurologic involvement where early in

tensive therapy is desirable. The isolation of an anti-pernicious anemia factor from the secretions of *Streptomyces griseus* is important in that this source may prove practical from the economical standpoint.

Vitamin B<sub>12</sub> is unique in that it is a cobalt-containing complex and has a characteristic purplish color. This places emphasis on the problem of the fundamental importance of cobalt as a trace substance in human nutrition.<sup>21</sup> Cobalt may be an element essential to the activity of vitamin B<sub>12</sub>; however, the cobaltous ion by itself does not appear to have any activity when tested by the microbiologic method.<sup>9</sup> Furthermore, West<sup>22</sup> treated two patients with pernicious anemia using cobalt acetate (single dose of 500  $\mu$ g) and cobalt chloride (single dose of 150  $\mu$ g) without hematologic response. Whether cobalt has any value in the treatment of other hematologic diseases is yet to be demonstrated. We have administered cobalt chloride to 5 cases of hypoplastic anemia and 3 cases with leukemia in doses of 10 to 25 mg daily (table 8). We have not noticed any significant hematologic changes which could be attributed to the administration of cobalt in these diseases and Burchenal<sup>23</sup> has had similar experiences in hypoplastic anemia, aplastic anemia and leukemia.

#### SUMMARY

1. A clinical remission in one case of pernicious anemia in relapse treated with 50  $\mu$ g of vitamin B<sub>12</sub> from liver is reported. The patient was followed for 114 days after two doses of 25  $\mu$ g were given on successive days and a peak of 3,900,000 erythrocytes occurred on the eighty-sixth day.

2. Preliminary observations are reported in 2 patients with pernicious anemia in relapse treated with a vitamin B<sub>12</sub> derived from *Streptomyces griseus*; the first patient who had no neurologic complaints received 32  $\mu$ g while the second was given two doses of 32  $\mu$ g each because of severe, subacute, combined degeneration. A good hematologic response and a satisfactory clinical remission occurred in both cases. There was definite improvement neurologically in the second case.

3. The administration of 32  $\mu$ g of vitamin B<sub>12</sub> derived from *Streptomyces griseus* to each of 5 cases of pernicious anemia in remission resulted in minor subjective and objective improvement.

#### CONCLUSIONS

1. Vitamin B<sub>12</sub> from liver and vitamin B<sub>12</sub> derived from *Streptomyces griseus* produce similar clinical results when dosages of the same magnitude are given to patients with pernicious anemia in relapse. Since the physical and chemical properties are also very similar this implies that these substances are closely related or identical.

2. The results obtained in this study are consistent with previous indications that vitamin B<sub>12</sub> is the single or at least the principal active anti-pernicious anemia factor in liver extract.

3. If the active factor can be prepared economically from cultures of *Streptomyces griseus*, this may prove a valuable source for the specific therapeutic agent in pernicious anemia and related macrocytic anemias.

4. The ingestion of cobalt chloride has little or no effect upon the blood levels of cases of hypoplastic anemia and leukemia.

## ADDENDUM

The purpose of the addendum is to discuss I the further progress of the eight cases reported above, II the presentation of three additional cases of pernicious anemia treated with vitamin B<sub>12</sub> (from *Streptomyces griseus*), III the administration of vitamin B<sub>12</sub> sublingually, and IV additional comments

## I Interval Report of Cases Reported (Above)

Patient	Blood Count				Further Treatment	Comment
	Date (1949)	Day after 1st dose of vitamin B <sub>12</sub>	Hb (%)	RBC		
Mrs. A. O. B.	1-26	114	68.5	3.2	Liver ext 15 $\mu$ weekly since 1-26	Previous peak not exceeded since liver extract was started
A. C. (Case 1)	3-30	82	75.2	3.75	None	Remission lasted less than 130 days Sublingually (see below)
	5-18	131	55.8	2.60	B <sub>12</sub> 200 $\mu$ g	
	5-20	133				
K. R. (Case 2)	2-8	27	45	2.2	B <sub>12</sub> 25 $\mu$ g	Further neurologic improvement (see below) Remission waning 5-17
	4-27	105	83	4.4	B <sub>12</sub> 50 $\mu$ g	
	5-17	125	61	3.18		
F. P. (Case 3)	2-23	53	83.1	3.85	Liver ext 15 $\mu$ weekly since 2-23	Treatment restarted because of paresthesias even though blood count was normal
M. S. (Case 4)	5-4	133	72.2	3.5	None	Satisfactory remission maintained
A. N. (Case 5)	3-9	70	77.9	4.0	Liver ext 15 $\mu$ weekly since 3-9	Treatment restarted because of weakness and paresthesias although blood count was normal
M. B. (Case 6)	5-11	140	73.2	3.52	None	Satisfactory remission maintained
V. S. (Case 7)	4-7	85	58	2.4	B <sub>12</sub> 50 $\mu$ g	Sublingual administration of vitamin B <sub>12</sub> (see below)
	4-14	92	68	3.1	B <sub>12</sub> 100 $\mu$ g	
	5-2	110	68	3.3		

Case II, Mrs. K. R. The results of treatment of Mrs. K. R. (Case II) deserve further mention. On Feb. 8, 1949, the blood levels had risen to 45 per cent hemoglobin and to 2,200,000 erythrocytes. At this time an additional 25  $\mu$ g of B<sub>12</sub> (from *Streptomyces griseus*) were given by injection because of the severity of the neurologic lesions. There was a continuation of the highly satisfactory course with good strength and appetite and further improvement of the neurologic manifestations. On April 27, 1949, the station gait and position sense were normal as were the deep tendon reflexes. Only faint Hoffman's and Babinski's signs were present. The vibration sense had reappeared at the upper end of the tibiae (although still subnormal) and was faintly perceptible at the ankles. The blood levels reached a peak of 83 per cent hemoglobin and 4,400,000 erythrocytes on April 27, 1949. However, three weeks later there were early signs of relapse with slight regression of the neurologic improvement and a drop in the blood levels.

to 61 per cent hemoglobin and 3 180 000 erythrocytes. The remission (produced by a total dose of 89  $\mu$ g of B<sub>12</sub>) lasted therefore over 100 days. A dose of 50  $\mu$ g of B<sub>12</sub> was given intramuscularly on May 17 1949.

## II Report of Three Additional Cases

**Case 8** M. McC. a 64 year old Irish woman was admitted to the Jefferson Hospital Feb. 15 1949 with pernicious anemia in relapse. In addition to the usual history of weakness fatigue dyspnea anorexia weight loss and sore tongue the patient had noted mild jaundice for three months. The patient had a smooth tongue cheilososis and a palpable liver. The only neurologic change was diminution of vibration sense at the left ankle. The blood levels on admission were 28.8 per cent (4.4 Gm) hemoglobin and 1 300 000 erythrocytes. There was a reticulocytosis of 10.5 per cent because of ingestion of liver pills just before admission. On Feb. 28 1949 when the reticulocyte level had dropped to 3.2 per cent 50  $\mu$ g of B<sub>12</sub> (from *Streptomyces griseus*) were given intramuscularly. The reticulocyte peak was 16.6 per cent on the 5th day. There was remarkable increase in strength and appetite and the jaundice disappeared. Normal vibration sense was restored. The maximum hemoglobin level (70.8 per cent) and erythrocyte count (3 510 000) occurred on April 13 1949 (44 days after injection). Two weeks later April 27 1949 the blood levels had dropped (hemoglobin—60 per cent erythrocytes—3 000 000). The patient was then given 50  $\mu$ g of vitamin B<sub>12</sub> sublingually (See below.)

**Case 9** V. P. a 36 year old Negress was admitted to the Jefferson Hospital on March 12 1949 with pernicious anemia in relapse. The main clinical features included gastrointestinal disturbances cardiovascular complaints sore tongue anorexia weakness headaches and weight loss. The blood count was hemoglobin 21.3 per cent (3.29 Gm/100 cc) erythrocytes 950 000 leukocytes 2 300 platelets 44 000 (per cu mm). The administration intramuscularly of 50  $\mu$ g of vitamin B<sub>12</sub> (from *Streptomyces griseus*) on March 15 1949 resulted in a reticulocyte peak of 39.2 per cent on the 6th day. The gastrointestinal complaints subsided within two days and the patient developed an excellent appetite. By April 20 1949 the atrophy of the tongue had completely disappeared as had also the cardiac signs and symptoms. Increase in strength paralleled the gradual rise of blood levels which reached 64.5 per cent hemoglobin and 3 800 000 erythrocytes on May 4 1949 the 45th postinjection day. The blood count was maintained at this level and the patient felt well when she was last seen on May 18 1949.

**Case 10** J. G. a 47 year old white man was admitted to the Jefferson Hospital March 2 1949 with a spastic unsteady gait and weakness of the lower extremities. A diagnosis of pernicious anemia in relapse (hemoglobin 35 per cent erythrocytes 1 400 000) had previously been made in March 1948 and a hematologic remission had been produced and maintained by regular injections of liver extract. The neurologic picture was complicated by an old spinal cord injury (incurred in 1938) for which he had been observed by the Neurology Service since 1946. This injury had resulted in an hypotonic bladder a residual partial Brown-Sequard syndrome on the left side at the level of T8 and a partial posterior-column syndrome with loss of vibration sense from the lower ribs down but intact position sense. The patient's spasticity had its onset with the anemia and had become progressively worse until the time of admission. Diagnosis was made of lateral-column disease secondary to pernicious anemia. On March 15 1949 50  $\mu$ g of vitamin B<sub>12</sub> (from *Streptomyces griseus*) were given intramuscularly and a dose of 25  $\mu$ g each week thereafter. There was an early improvement in steadiness of gait and a gradual decrease of spasticity. The hyperactivity of the reflexes lessened as did the intensity of the pathologic reflexes in all extremities. At the end of eight weeks the functional performance was reasonably good. There was no improvement of the changes resulting from the old injury.

## III Sublingual Administration of Vitamin B<sub>12</sub>

Pernicious anemia seems to be a disease of impaired absorption (through the gastrointestinal mucosa) of fats carbohydrates proteins<sup>11</sup> and certain vitamins, particularly vitamin B<sub>12</sub>. Hall et al.<sup>12</sup> have shown that dosages (25  $\mu$ g) of B<sub>12</sub> which are effective when given intramuscularly, are ineffective when given orally, unless normal gastric juice is added. This suggests that the intrinsic factor acts merely as a carrier or absorber of B<sub>12</sub> through the gastrointestinal mucosa.

However, West<sup>16</sup> stated that large doses (600  $\mu\text{g}$ ) of  $\text{B}_{12}$  given orally will produce a maximum reticulocyte response. This would imply either that patients with pernicious anemia make small but insufficient quantities of intrinsic factor (permitting only partial absorption of available  $\text{B}_{12}$ ), or that  $\text{B}_{12}$  in relatively high concentration is absorbed by mass action (despite the lack of absorber or intrinsic factor). Realizing that saliva does not contain intrinsic factor, we were interested in determining if vitamin  $\text{B}_{12}$  concentrated on a small area of oral mucosa would be appreciably absorbed. Hence three patients were given  $\text{B}_{12}$  sublingually.

*Case 1.* A. C. On May 18, 1949 the blood levels had dropped to 55.8 per cent hemoglobin and 2,600,000 erythrocytes; the reticulocyte count was 0.7 per cent. On May 20, 1949 the patient received sublingually 100  $\mu\text{g}$  of vitamin  $\text{B}_{12}$ . The reticulocyte level rose to 4.2 per cent on May 23, 1949.

*Case 7.* V. S. was given 50  $\mu\text{g}$  of vitamin  $\text{B}_{12}$  sublingually on April 7, 1949 at which time the hemoglobin was 58 per cent, the erythrocyte count 2,400,000 and the patient complained of weakness and parasthesias of the hands and feet. On the 5th day after the administration the reticulocyte level had increased to 5.2 per cent. The patient felt much improved. On April 14, 1949 another 100  $\mu\text{g}$  were given sublingually. On May 2, 1949 the patient continued to feel well and the blood count was 68 per cent hemoglobin with 3,300,000 erythrocytes per cu. mm.

*Case 8.* M. McC. was given 50  $\mu\text{g}$  of vitamin  $\text{B}_{12}$  sublingually on April 27, 1949 when it appeared that her count had started to drop. The hemoglobin at this time was 60.6 per cent (9.33 Gm) and the erythrocyte count was 3,000,000. The patient noticed stiffness of the hands and parasthesias and there was diminished vibration sense again at the left ankle. The tongue showed early atrophic changes. There was no reticulocytosis after the sublingual administration. However, the patient felt much better. One week later the stiffness of the hands had subsided but the decreased vibration sense persisted. In two weeks, May 11, 1949 the hemoglobin had risen to 69.2 per cent (11.67 Gm) and the erythrocyte count to 3,800,000. The vibration sense in the ankle became normal although occasional parasthesias were still present. The patient felt well except for a sore tongue which had developed during the second week. The end of the tongue was beefy red and the central and posterior portions atrophic. At this time, May 11, 1949 50  $\mu\text{g}$  of vitamin  $\text{B}_{12}$  were given intramuscularly. Again there was noted no reticulocytosis on the 5th day. The glossitis disappeared one week after injection.

#### IV. Comments

It is interesting to note that Addison exactly 100 years ago first accurately described pernicious anemia.<sup>17</sup> The isolation of the antipernicious anemia factor (the most potent therapeutic agent known to man at present) is a most appropriate centennial event.

Allowing for variations in the degree and type of relapse and in the individuals, responsiveness it can be estimated that the injection of 50 to 100  $\mu\text{g}$  of vitamin  $\text{B}_{12}$  is capable of producing a remission of pernicious anemia lasting 50 to 100 days, about 50  $\mu\text{g}$  given to a patient in remission will maintain the remission 70 to 120 days. The general complaints (weakness, fatigue and glossitis) and neurologic complaints (parasthesias and stiffness) appeared more difficult to control than the blood levels.

Treatment of pernicious anemia with  $\text{B}_{12}$  (or liver extract) occasionally results in iron deficiency during the development of remission. Thus one of our patients (K. R.) developed hypochromia of erythrocytes which was overcome with the use

of intravenously administered iron (saccharated iron oxide\*) Other deficiencies during remission in pernicious anemia are indicated by the work of Brown<sup>18</sup> who found that glossitis (and other lesions) developing during liver extract therapy required specific treatment, with pantothenic acid, nicotinic acid, riboflavin or folic acid Glossitis which developed in one of our patients, M McC, (while remission was complete in all other respects) responded well to an additional dose of B<sub>12</sub> As yet there have been no reported failures of glossitis to respond to adequate treatment with B<sub>12</sub>

The results of the sublingual therapy were inconclusive because of the difficulty in evaluating response in patients with partial remission Slight reticulocytosis occurred in two of the three trials and a definite clinical improvement seemed evident in each case The degree of response and the sites (gastric or sublingual) of absorption were uncertain

# THE EFFECT OF VARIOUS ANTICOAGULANTS ON THE SPECIFIC GRAVITY OF BLOOD AND OF PLASMA, AND ON THE HEMATOCRIT

By PAUL L. McLAIN, M.D., AND C. H. WILLIAM RUIE, M.D.,  
WITH GEORGE J. PASTORIUS, M.D.

THE INTRODUCTION of rapid, simple methods for measuring the specific gravity of body fluids<sup>1-3</sup> has led to a growing appreciation of the usefulness of such measurements, particularly as applied to blood and plasma<sup>2-10</sup>. Although it is not difficult to measure the specific gravity of blood prior to coagulation, the comparable treatment of plasma requires special facilities for rapid sedimentation of the corpuscles. In general, the measurements are carried out much more conveniently on samples which have been defibrinated or in which coagulation has been prevented by the use of various chemicals. The influence of certain anticoagulant procedures on the specific gravity of blood and plasma has been reported,<sup>2, 11, 12</sup> but greater emphasis has been placed upon the effects on red cell volume<sup>12-24</sup>. In the observations here reported, the specific gravity of defibrinated, heparinized, oxalated, and citrated blood, as well as that of the serum or plasma from blood so treated, was compared with the specific gravity of an aliquot of the same sample, untreated and prior to coagulation. Similar comparisons were made for relative red cell volumes by hematocrit.

## MATERIAL, PROCEDURE AND METHODS

All observations were made on arterial blood freshly drawn from rabbits. The animals were anesthetized lightly with ether and a large bore hypodermic needle was tied into one of the carotid arteries exposed in the neck. Approximately 20 ml. of blood were withdrawn into a syringe and the blood was then quickly transferred in measured amounts to small, appropriately prepared test tubes. The drawing and transfer of the blood required only a few seconds; hence uniformity of the sample was assured.

Plasma from untreated blood was obtained by centrifugalizing freshly drawn blood for thirty seconds in an angle centrifuge at about 12,000 revolutions per minute (mean radius 6.7 cm.). Aliquots for defibrination were stirred with fine nickel silver wires for the required length of time, usually about five minutes. Samples for chemical anticoagulant treatment were mixed promptly with the proper amounts of reagent previously placed in the receptacles. The anticoagulants used with their respective amounts for each ml. of blood, were as follows: heparin dry, 0.1 mg. (10 units); heparin, solution 0.01 ml. (equivalent to 0.1 mg. of dry heparin); sodium citrate powdered 5.0 mg.; potassium oxalate, powdered 2.0 mg.; potassium oxalate 1.6 per cent solution 0.125 ml. (equivalent to 2.0 mg. of dry potassium oxalate); ammonium potassium oxalate mixture<sup>25</sup> 3.2 by weight 1.0 mg.

The specific gravity (25/25 C.) of the blood and of the plasma or serum for each of the above conditions was measured by a modification of the falling drop method of Barbour and Hamilton.<sup>1</sup> Relative volumes of red cells and plasma or serum were measured centrifugally by an hematocrit of the Daland<sup>26</sup> type operated at 12,000 r.p.m. and 4.7 cm. effective radius (R.C.F. approximately 7,500 x G.) until constant sediment volumes were obtained.

From the Department of Physiology and Pharmacology, School of Medicine, University of Pittsburgh, Pittsburgh, Penna.

Presented in part before the Twenty ninth Annual Meeting of the Federation of American Societies for Experimental Biology, Boston, Mass., March 31-April 4, 1942.

## RESULTS AND DISCUSSION

Analysis of the data by the usual statistical methods showed that, for the distributions obtained, demonstration of heterogeneity among the various series of observations required differences far in excess of the established experimental errors for the methods employed. For this reason, the occurrence of certain minimum differences between treated and untreated aliquots of individual samples was considered a more reliable basis for analysis than the conventional difference between means, especially for limited series. The tables, therefore, show the frequency and direction (a) of all changes which occurred in the individual comparisons, and (b) of all changes in excess of somewhat arbitrary limits, chosen to represent changes measurable with certainty by the methods employed, yet of limited or doubtful significance when interpreted clinically, especially in view of the magnitude of normal diurnal variations. In addition, mean and algebraic mean changes are tabulated.

*Effect of Anticoagulant Procedures on Specific Gravity*

**Blood.** The first section of table 1 summarizes the changes in specific gravity of whole blood associated with the various anticoagulant procedures. All but two of these produced mean changes in excess of 0.0004, the limit chosen as representing a significant difference from the control specific gravity. The greatest changes, as well as the most frequent and most consistent in direction, occurred under the influence of sodium citrate and dry potassium oxalate. Both of these chemicals, in the amounts employed, increased the specific gravity of blood at every trial. Further, all but one such increase exceeded 0.0004. Dry heparin increased the specific gravity in a significant majority of cases, though an occasional decrease occurred. Increases greater than 0.0004 were noted in about half the cases, and the algebraic mean change was positive in sign and just below the limit of significance. Heparin solution, on the other hand, decreased the specific gravity in all but one instance, and more than two-thirds of these decreases were greater than 0.0004. Correction of the results for the volume and specific gravity of the heparin solution (not shown in the table) materially reduced the number of significant changes, and reduced the mean change by approximately one-half. However, such correction is awkward and impractical for routine work. Potassium oxalate in 1.6 per cent solution is generally considered to be isosmotic with blood,<sup>21</sup> and should therefore produce little or no change in corpuscle size. Further, it should be possible to correct observed specific gravities for the volume and specific gravity of the oxalate solution added to blood as an anticoagulant. In this series, values so corrected were lower than the controls by more than 0.0004 in half the trials and within 0.0004 of the control specific gravity in the remainder. The correction was therefore only 50 per cent effective. The Heller-Paul oxalate mixture caused increases and decreases in specific gravity with almost equal frequency. However, relatively few of these changes exceeded 0.0004, and the algebraic mean change was +0.0001, which indicates the best distribution of changes in the entire series of observations. Defibrination caused the smallest mean change in specific gravity of blood and gave the greatest frequency of values identical with the control. With regard to the fre-

quency of significant changes, defibrination was very nearly equivalent to oxalate mixture

Of the anticoagulant procedures tested, then, defibrination and addition of Heller-Paul oxalate mixture caused the smallest and least frequent changes in the specific gravity of whole blood. Since both positive and negative changes occurred,

\* For corpuscles read 0.0029 in place of 0.0004 (see text)

† Observed specific gravities were corrected for volume and specific gravity of added solution.

‡ Specific gravities of corpuscles were calculated

and since the mean change was not significant from a practical standpoint, correction of observed specific gravities for the effects of these two procedures is not recommended

*Plasma* The second section of table 1 shows the influence of the various anticoagulant methods on the specific gravity of plasma. As in the case of whole blood, sodium citrate and dry potassium oxalate increased the specific gravity in all trials and to a highly significant degree. Oxalate mixture, which had insignificant effects on the specific gravity of whole blood, increased that of plasma markedly in all

cases Dry heparin increased the specific gravity of plasma in a clear majority of instances, the effect being slightly more pronounced on plasma than on whole blood. The effect of oxalate solution, after appropriate correction, was to increase the specific gravity in excess of 0.0004 in half the cases, the mean change being 0.00061. While serum from defibrinated blood had a lower specific gravity than that of the corresponding plasma in nearly 80 per cent of trials, the differences exceeded 0.0004 in only 22 per cent, the mean change being 0.00029. There were no direct comparisons between untreated plasma and that resulting from the use of heparin solution as an anticoagulant. However, the mean difference between such plasma and serum from defibrinated blood was insignificant. Since dry heparin increased the specific gravity of plasma while defibrination tended to reduce it, the heparin-solution as here employed seemed satisfactory for preservation of the specific gravity of plasma, but not of blood.

\* Observed values corrected for volume of added solution

**Corpuscles** The specific gravity of red cells was calculated from the observed specific gravities of whole blood and plasma, and the relative volumes of cells and plasma obtained by hematocrit. The results were therefore influenced by the combined errors of the basic measurements. Computations indicated that a change in corpuscle specific gravity of 0.003 or greater should be detectable with certainty even though the contributory errors might be additive. All changes in corpuscle specific gravity greater than 0.0029 were, hence, considered significant.

The third section of table 1 shows that sodium citrate and dry potassium oxalate increased the specific gravity of corpuscles in all observations. The remaining anticoagulant procedures produced few significant effects.

#### *Effect of Anticoagulant Procedures on the Relative Volumes of Corpuscles and Plasma*

The hematocrit employed in this study was capable of revealing with certainty changes in excess of 1.0 volume per cent. Among the anticoagulant procedures, sodium citrate and dry potassium oxalate consistently produced marked shrinkage of the red cell volume, as shown in table 2. Among the other methods, only occasional changes in excess of 1.0 volume per cent occurred. No such changes were

noted with oxalate mixture, dry heparin, or heparin solution, and only one with 1.6 per cent potassium oxalate solution after correction for volume of added fluid. Defibrination tended to increase the hematocrit results, though the change was less than 1.0 volume per cent in over three-fourths of the trials. The best methods for preservation of cell-plasma volume relationships were oxalate mixture and isosmotic potassium oxalate solution.

#### SUMMARY

The effects of several commonly employed anticoagulant procedures on the specific gravity of blood and of plasma, and on the relative red cell volume, were studied in freshly drawn samples of arterial blood from rabbits. Measurements on treated blood, or its fluid component, were compared with corresponding results on portions of the same samples without treatment and prior to coagulation.

Satisfactory preservation of the specific gravity of whole blood was obtained by defibrination or by the use of ammonium-potassium oxalate mixture.

Satisfactory preservation of the specific gravity of plasma was obtained by defibrination or by the use of heparin solution.

The relative volume of red cells was essentially unaltered by the use of dry heparin, oxalate mixture, 1.6 per cent solution of potassium oxalate, or by defibrination.

Dry potassium oxalate and sodium citrate caused marked changes, increasing the specific gravity of blood and of plasma, and shrinking the red cells.

Dry heparin caused significant increases in the specific gravity of blood and of plasma.

Ammonium-potassium oxalate mixture increased the specific gravity of plasma markedly and consistently.

# THE KELL-CELLANO (K-k) GENETIC SYSTEM OF HUMAN BLOOD FACTORS

By PHILIP LEVINE, M D , MILTON WIGOD, M A , ABBY M BACKER, M D ,  
AND RUTH PONDER, B A

A NEW agglutinable factor of human blood was recently discovered with the aid of an antibody, an agglutinin, which is remarkable for its high incidence of positive reactions, 99.8 per cent, in white individuals (U S A ) This antibody was found in a mother, Mrs Cellano, whose infant had a mild form of hemolytic disease Accordingly, the antibody will be referred to as anti-Cellano and its corresponding agglutininogen as Cellano

A study of the family of an individual from among the 0.2 per cent Cellano negative group revealed the hereditary nature of the Cellano factor \* Of the eight children, three were Cellano negative Since both parents were Cellano positive, they were presumed to be heterozygous Assuming two allelic genes, one determining Cellano positive and the other Cellano negative, the following values for the three genotypes were derived †

Homozygous Cellano Positive	91.2%
Heterozygous Cellano Positive	8.6%
Homozygous Cellano Negative	0.2%

Because of the possible analogy to the M-N and the three Rh-Hr systems, the authors considered the existence of another genetically related blood property present in the Cellano negative and Cellano heterozygous groups Thus, this theoretic blood factor should have incidences of about 8.8 per cent Two types of antibodies giving very similar incidences (anti-Lutheran 8 per cent and anti-Kell 7 per cent) had been observed by Coombs, Mourant, Race and their co-workers <sup>2,3,4</sup> An analysis of the results with anti-Cellano and two specimens of anti-Kell sera on the above-mentioned family reveals the significant conclusion that the Cellano and Kell antigens are genetic alleles (table 1)

For the sake of uniformity, the letters K and k, already employed by the British workers for the genes determining Kell positive and Kell negative reactions, respectively, will be retained The results given in table 1 indicate that the gene k can now be considered as indicating the presence of the Cellano factor

As shown in table 1, both parents are heterozygous (Kk) and each is capable of transmitting the genes K and k to their offspring Such matings, which occur very rarely, i e , 8.6 per cent  $\times$  8.6 per cent or one in 135, are most useful for analysis of

From the Rh Blood Testing Laboratory Ortho Research Foundation Raritan New Jersey and the Nassau Hospital Laboratory Mineola N Y

\* See table 1 and the paper by Levine et al <sup>1</sup>

† The incidence of the gene for Cellano negative =  $\sqrt{0.002} = 0.045$  or 4.5% while the incidence of the gene for Cellano positive =  $1 - 0.045 = 0.955$  or 95.5% The three values given above are derived from the equation  $(.955 + .045)^2$

factors which have either very low or very high incidences. Thus, Cellano negatives of genotype KK (homozygous Kell) which should occur in 25 per cent of the offspring, were found in three of the eight children in contrast to 0.2 per cent in a random population. Similarly, Kell positive (KK and Kk) which should occur in 75 per cent of the offspring of heterozygous parents, were found in six of the eight children in contrast to 88 per cent in a random population.

Further evidence for the allelic nature of the Kell and Cellano factors was obtained in a study of the five siblings of another Cellano negative individual. Two of the five are Cellano negative and four are Kell positive. These findings are presented in table 2.

TABLE 1

	Anti Kell Anti Lazarus	Anti Cellano	Genotype
Father Mr J. Kul Sr	+	+	Kk
Mother Mrs M. Kul	+	+	Kk
Children 1 John	+	+	Kk
2 Julian	+	o	KK
3 Mrs A. G.	o	+	kk
4 Mrs I. S.	+	+	Kk
5 Mrs A. V.	+	o	KK
6 Frank	+	o	KK
7 Andrew	+	+	Kk
8 Josephine	o	+	kk
Controls Mrs Cellano	+	o	KK
Mr Lazarus	+	+	Kk
Mrs Lazarus	o	+	kk
Jeffrey Lazarus	o	+	kk

As in the Kul family, the parents of the five siblings must be heterozygous for both factors and this was confirmed when their bloods were subsequently tested.

In the first publication of the Kell antigen, its frequency was given as 7 per cent, while the serum studied by Wiener and Sonn reacted on 13 per cent. \* Sanger, Race and their co-workers now report a larger series with an incidence of 10.17 per cent positive reactions. The calculated incidences of three genotypes based on the latter value and on the value 99.8 per cent for the Cellano factor are compared in table 3.

The close agreement of these values further supports the view that the genes for the Kell and Cellano factors are allelomorphous to each other. As in the case of the M-N and the three Rh-Hr systems (Dd, Cc, and Ee), the three genotypes resulting from the interaction of these two genes correspond to the three phenotypes identified by parallel tests with the Kell and Cellano antibodies. A type of blood which fails to react with both sera has not been observed.

Sera containing anti-Cellano antibodies are necessarily very rare, while the anti-Kell type of antibody has been observed at least six times. A list of these follows.

\* The identification of this antibody as anti Kell was made by Dr. Race.

1 Kell	Coombs Mourant and Race <sup>1</sup>
2 Si	Wiener and Sonn <sup>2</sup>
3 Drizen	Sanger and Abelson <sup>3</sup>
4 And	Dunsford <sup>4</sup>
5 Lazarus	Levine Rauch and Block <sup>5</sup>
6 P L	Vogel and Rosenfeld <sup>10</sup>

TABLE 2

	Anti K (Anti Lazarus)	Anti k (Anti Cellano)	Genotype
Father Mr H Mc	+	+	Kk
Mother Mrs L. Mc	+	+	Kk
Children 1 Mrs B M	+	o	KK
2 J G Mc	+	+	Kk
3 E. V Mc	o	+	kk
4 Mrs A R	+	+	Kk
5 Mrs V S	+	o	KK

TABLE 3

	Anti Kell (Anti K)	Genotype	Anti Cellano (Anti k)
Kell positive	$\left\{ \begin{array}{l} 89 \ 83 \\ 9 \ 90 \\ 0 \ 27 \end{array} \right.$	$\left\{ \begin{array}{l} Kk \\ Kk \\ KK \end{array} \right.$	$\left. \begin{array}{l} 91 \ 2 \\ 8 \ 6 \\ 0 \ 2 \end{array} \right\} \text{Cellano positive}$

The greater incidence of anti-Kell type of sera is not surprising since incompatible matings for the Kell factor occur in  $8 \ 8 \times 91 \ 2$ , or  $1 \ 12 \ 5$  in contrast to a value of  $99 \ 8 \times 0 \ 2$  or  $1 \ 500$  for the Cellano factor. Thus, the opportunity for the production of anti-Kell sera is 40 times greater than for anti-Cellano.

Anti-Kell type of antibody may be missed in routine tests for isoimmunization, unless the mother's serum is tested against her husband's cells, suspended in bovine albumin, and with the Coombs technic. These procedures are essential for all instances in which isoimmunization may be brought about by a blood factor characterized by a low incidence in the general population. Anti-Kell may be differentiated from anti-Lutheran since the latter antibody does not give a positive Coombs test and, in contrast to anti-Kell, its reactions are stronger at lower temperatures than at 37°C.

Antibody of the anti-Cellano type may be expected if the serum gives an unusually high incidence of positive reactions. It is important, however, to exclude the anti-e (anti-hr<sup>+</sup>) antibody which gives about 97 per cent positive reactions, or the coexistence of more than one antibody. The latter possibility may be tested by suitable absorption experiments with carefully selected bloods of known antigenic structure.

Extensive racial and genetic studies will be carried out when larger supplies of these two antibodies become available. Preliminary experiments have shown that the Kell and Cellano factors are not antigenic in rabbits.

Although preliminary data indicate that Kell and Cellano factors are not related to other blood properties, more comprehensive studies are required to exclude the possibility of linkage.

#### ACKNOWLEDGMENT

The authors are indebted to R. R. Race for a sample of anti Kell serum. With the aid of this specimen it was possible to identify another antibody (anti Lazarus) studied in our laboratory since 1946 as of the Kell variety. This patient had two stillbirths due to hemolytic disease of the fetus and one surviving child who is Kell or Lazarus negative, the husband being heterozygous (cf. controls in table 1). The authors are also indebted to Mr. Benson Rosenberg, Elizabeth, N. J. for the blood specimens of the Kul family and to Dr. W. E. Hoffman, Charleston, W. Va. for the Mc family.

The tests with anti Kell were made with the aid of Coombs anti human serum. Identical results with anti Lazarus serum were obtained using both the Coombs technique and albumin suspended cells. The test with anti-Cellano were made with saline suspended cells.

## EDITORIAL

### AUTO-IMMUNIZATION

BETWEEN 1907 and 1914, the [French workers Chauffard<sup>1</sup> Widal and their collaborators discriminated sharply between hereditary and acquired types of hemolytic anemia. The rivalry between these two groups was keen, but from it sprang many new concepts and diagnostic tests. Widal, Abrami, and Brule found auto-agglutinins in each of their cases of acquired hemolytic anemia and pointed to the diagnostic value of this finding. The significance of their observations was lost for many years, and for a long period (approximately between 1920 to 1940) many observers stated that no real distinction could be made between hereditary and acquired forms. In the last decade, however, observations have accumulated which not only prove that hemolytic anemia may be acquired but which go far towards indicating some of the mechanisms involved.

The finding of an immune type of iso-hemolysin in three cases of acute hemolytic anemia led us to suspect that this was etiologically related to the excessive degree of hemolysis present.<sup>2</sup> This was borne out by experimental observations with hetero-hemolysins.<sup>3</sup> Guinea pig red cells, injected into rabbits, resulted in the development of anti-guinea pig hemolytic serum. When this serum was then injected in guinea-pigs, spherocytosis and acute hemolytic anemia developed. The observation was made that the small spherocytes were mature red cells and that the large red cells present were reticulocytes. This biphasic type of red cell population was considered to be distinctive for hemolytic anemia and the deduction was made that it was due to (a) hemolytic activity of hemolysin acting on mature red cells and producing spherocytosis, and (b) to regenerative activity on the part of the marrow, resulting in reticulocytosis. The disease hemolytic anemia was considered to be an active rather than a passive process, and not due to a marrow dysfunction.

Later, when the mechanisms for acute hemolytic disease of the newborn (erythroblastosis fetalis) were studied, it was apparent that Rh iso-antibody as developed by the Rh negative mother was responsible for injuring and thus destroying the Rh positive red cells of the fetus. Some Rh antibodies could be detected in salt solution, whereas in other cases, bovine albumin or plasma had to be used to demonstrate the agglutinin (blocking or univalent antibodies). With the use of another test developed later by Coombs, Mourant and Race,<sup>4</sup> it was apparent that antibody was firmly affixed (coated) to the red cell and could not be readily removed even with repeated washings of salt solution.

*Hetero-immunization* is rather readily understood: red cells from one species of animal (X-antigen) are injected into the circulation of another species: the second animal builds up a hetero-antibody (anti-X), this antibody can then injure the red cells of animals of the X-type and cause hemolytic anemia. Iso-immunization, too, seems fairly simple to comprehend, at least in its superficial aspects. Here, an individual lacking a specific factor (such as Rh) can be immunized by the red cells (antigen) of another individual of the same species, with the production of

an antibody When this antibody (anti-Rh) is then re-injected into the circulation of an individual with Rh positive red cells, antibody is adsorbed by the red cells. These become injured, i.e., spherocytic, or agglutinated, and are then removed from the circulation either by way of mechanical trauma or by splenic hemolysis.

In most cases of acquired hemolytic anemia other than in the type seen in the newborn, *auto*-immunization appears to be the central feature. The cause for this phenomenon, in which the individual's own red cells apparently develop antigenic qualities, thus producing an auto-antibody, is quite obscure. In any event, there can be little doubt that in practically all cases of acquired hemolytic anemia not due specifically to bacteria, parasites, chemicals or other definite factors, i.e., in the idiopathic cases, the plasma contains an *auto*-antibody which acts against the individual's own red cells. This is also an *iso*-antibody, since it reacts against all types of human red cells and can be detected both by the use of bovine albumin as a testing fluid and by the Coombs anti-globulin technic. Evidence is at hand indicating that this antibody causes a shortening of red cell survival time of foreign transfused red cells and of the individual's as well. Recent studies in our laboratory reveal a striking correlation between three tests: (1) *iso*- and auto-antibody as detected by the bovine albumin technic, (2) the anti-globulin test, and (3) the red cell survival time as determined by the Ashby technic. We find that auto-antibody is often higher in concentration than is *iso*-antibody.

Auto-immunization appears to be the prime factor in acquired hemolytic anemia. It occurs not only in the idiopathic cases, but in the symptomatic hemolytic anemia of such conditions as chronic lymphocytic leukemia. In the last three cases of this disorder we have observed, an auto-antibody of agglutinin type was demonstrable. As a result of auto-immunization, various types of antibodies may develop. It appears probable that antibody, affixing itself to the mature red cells of the affected individual, causes agglutination and other disturbances of the red cell membrane with resultant spherocytosis. The highest concentrations of antibody are associated with the greatest degrees of spherocytosis. These sensitized red cells are then acted upon either by complement, causing hemolysis, or more often are destroyed by the mechanical trauma of the circulation or selectively removed from the circulation by the spleen.

Splenectomy in acquired hemolytic anemia may or may not remove the largest single production center for auto-antibody formation, in any event, the chief spherocyte-destroying organ is removed. It is well to realize that splenectomy may be either wholly or partially ineffective, since continued production of antibody may occur. Future progress in acquired hemolytic anemia, which seems to be on the increase, lies in determining why auto-immunization develops and how it may be controlled.

## ANEMIA

**INCIDENCE OF SICKLE CELL ANEMIA IN THE NEWBORN NEGRO INFANT** R. B. Scott, R. P. Crawford and M. Jenkins. From the Division of Pediatrics, Howard University School of Medicine and the Pediatric Service of Freedmen's Hospital, Washington, D. C. *Am J Dis Child* 75: 842-849, 1948

Two hundred and sixty-two newborn Negro infants were tested for sickling trait by the cover slip method on the first, third and fifth days of life. Positive reactions were obtained in nine or 3.4 per cent as compared to sixteen or 7.6 per cent in a group of 209 older children (one week to eleven years) similarly tested. Three of the newborns with sickling trait were examined at a subsequent date (seven to seven teen months) and the degree of sickling in each was found to be greater. No cases of sickle cell anemia were present in the group of newborns.

The factors which may contribute to the suppression of sickling trait in early infancy and to the lower incidence of active sickle cell disease in childhood are discussed. It is possible that further study using one of the more recently developed and sensitive tests or, as the authors suggest, by the alteration of the chemical composition of the blood of young infants, may furnish an answer to this latency phenomenon and perhaps even aid in determining which patients with the trait will develop anemia and why.

H. B. M.

**SICKLE CELL DISEASE STUDIED BY MEASURING THE SURVIVAL OF TRANSFUSED RED BLOOD CELLS** S. T. E. Callender, J. F. Nickel, C. V. Moore and E. O. Powell. From the Department of Internal Medicine, Washington University and Barnes Hospital, St. Louis, Mo. *J. Lab. & Clin. Med.* 34: 90-104, 1949

The Ashby technic of differential agglutination was used to study the survival of transfused cells in relation to sickle cell disease. Normal red cells transfused to patients with sickle cell anemia showed a normal survival time. Red cells from patients with sickle cell anemia transfused to normal recipient subjects showed a shortened average time of survival. Red cells from healthy donors with the sickle cell trait transfused to normal recipient subjects and to a patient with sickle cell anemia showed a normal survival time. The findings indicate that the defect in sickle cell anemia is inherent in the red blood cell. There is evidence to suggest that sickling is not a function of age of the cell but that the cells in sickle cell anemia vary constitutionally in their liability to sickle. The authors suggest that the difference between the anemia and the trait is qualitative and not simply one of degree.

G. E. C.

**DETECTION OF MILD TYPES OF MEDITERRANEAN (COOLEY'S) ANEMIA** C. H. Smith. From the New York Hospital and the Department of Pediatrics, Cornell University Medical College, New York, N. Y. *Am J Dis Child* 75: 505-527, 1948

A study of the blood of 181 persons in 47 families with Cooley's anemia revealed that asymptomatic individuals with Cooley's trait or the mild form of the disease were surprisingly common in New York City.

The diagnostic hematologic procedures employed and the characteristic blood changes are described in detail. The author stresses the importance of the hematocrit as a diagnostic procedure and of the findings of increased resistance of red cells to hemolysis in hypotonic solutions of sodium chloride, stippled red cells and the presence of hypochromic macrocytes despite the tendency to microcytosis.

The hereditary aspects of this disease remain a subject of controversy although perhaps the majority of investigators currently favor the hypothesis that the mild form results from heterozygosity of an inherited factor which when homozygous causes true Cooley's anemia. While the author's finding of characteristic hematologic abnormalities in healthy members of the families of affected children (both parents in every case of a severely anemic child) supports the view of a dominant hereditary factor, he does not consider this limited study conclusive evidence of such a genetic relationship. He does, however, stress the importance of the mild form of the disease and of the need for more widespread detection of these asymptomatic carriers who are a potential source of hereditary transmission of the overt form of the disease.

H. B. M.

**SURVIVAL OF TRANSFUSED ERYTHROCYTES FROM A DONOR WITH NOCTURNAL HAEMOGLOBINURIA** *J. V. Dineen and P. L. Mellison* From the Department of Clinical Pathology and the Medical Research Council Blood Transfusion Research Unit and Department of Obstetrics, Post-Graduate Medical School of London, England. *Lancet* 1: 397-392, 1949.

Red blood cells from a patient with paroxysmal nocturnal hemoglobinuria were transfused (1) to an adult with rheumatoid arthritis and (2) to an anemic premature infant who received at the same time some normal adult blood. Survival of both normal and abnormal erythrocytes was followed by the Ashby technique. The cells from nocturnal hemoglobinuria were destroyed more rapidly than normal especially in the adult recipient. This fitted in well with the *in vitro* observation that the baby's serum showed less hemolytic activity than the adult and 6 other infant sera tested against the patient's red blood cells.

Both the *in vitro* studies and the transfusion experiments suggest that the red cells in paroxysmal nocturnal hemoglobinuria vary in susceptibility to hemolysis. This variation does not appear to be related to age of the cells.

S. C.

**PAROXYSMAL COLD HAEMOGLOBINURIA OF NON-SYPHILITIC TYPE** *L. K. Mallet and M. D. Hickey* From the Mater Misericordiae Hospital, Dublin, Eire. *Lancet* 1: 387-390, 1949.

This is a full report of a well investigated case of paroxysmal cold hemoglobinuria associated with chronic hemolytic anemia and Raynaud phenomenon. There was no evidence of syphilis and the Donath-Landsteiner reaction was negative. A high titer cold agglutinin active over a wide thermal range was constantly present and the mechanical fragility of the patient's red cells was increased. He died after four years observation of urinary infection. Necropsy findings are reported.

S. C.

**HEMOLYSIS DURING TRANSURETHRAL PROSTATIC RESECTION** *C. L. Bjorn and L. F. Greene* From the Section on Urology, Mayo Foundation and Mayo Clinic, Rochester, Minn. *Surg., Gynec. & Obst.* 89: 369-375, 1949.

The incidence of hemoglobinemia following transurethral resection in a series of 100 cases selected at random was 56 per cent. The criterion used for hemoglobinemia in this study was a concentration of more than 25 mg. of hemoglobin per 100 cc. of plasma. As is pointed out, this concentration is somewhat higher than that used by other investigators who have reported a higher incidence of hemoglobinemia in similar although smaller case studies.

Excessive bleeding, the weight of the tissue removed, and the difficulty of resection appeared to be the significant surgical factors in inducing hemolysis, presumably by allowing much larger amounts of irrigating fluid (sterile water in this series) to wash into the circulation through venous sinuses. An analysis of postoperative reactions showed that gastrointestinal symptoms occurred twice as frequently in patients who had high concentrations of plasma hemoglobin as in those with no significant hemolysis. It is of interest that none of the patients experienced a postoperative chill, that the incidence of fever was greater in the group without hemolysis, and that there were no instances of postoperative oliguria other than one patient without significant hemoglobinemia in whom the oliguria was attributed to cardiac failure. Only six patients in this series had more than 500 mg. of hemoglobin per 100 cc. of plasma (one patient had 1,000 mg.). While levels of plasma hemoglobin higher than this may induce renal insufficiency, this

study of a statistically significant number of patients indicates that the concentration of hemoglobin-mia usually encountered during transurethral resection is not sufficient to be harmful

**MEGALOCYTIC ANAEMIAS** *J F Wilkinson* From the Department of Haematology Manchester Royal Infirmary England *Lancet* 1 49-55 291-296 336-340 1949

These Oliver Sharpey lectures given at the Royal College of Physicians London in March 1948 give a general review of megalocytic anemias colored by the author's own views and experience. As they were delivered a year ago there is no mention of work resulting from the discovery of vitamin B<sub>12</sub>. There is an initial summary of what was then known of the stomach principal extrinsic factor the liver principal and folic acid with emphasis on the work done by the author and his colleagues on the stomach factor. A discussion of the various types of megaloblastic anemia and the results of therapy follow. Finally the prognosis and incidence of cancer and other complications in pernicious anemia is discussed in relation to Wilkinson's own carefully observed series of 1 600 patients.

Some of the views expressed here of the relative inefficacy of some types of liver preparations particularly wartime and postwar British extracts have been challenged and the suggestion made that a lowered protein intake in the diet is a more relevant factor in suboptimal responses (*G E Shaw Lancet* 1 345-346 1949).

S C

**SEVERE ANAEMIA IN INDIAN SEPOYS (REFRACTORY TROPICAL MACROCYTIC ANAEMIA)** *R Passmore* From Indian Medical Service *Tr Roy Soc Trop Med & Hyg* 42 367-380 1949

One hundred and twenty seven cases of severe sometimes fatal and frequently refractory anemia were observed among sepoys serving in Assam and Eastern Bengal. Probable contributory factors were inadequate military hygiene recent malarial infection and malnutrition although evidence of these was not constantly present. Most of the blood examinations showed a macrocytic and either ortho- or hypochromic anemia. The bone marrow showed an increase in red cell precursors and an apparent shift to earlier forms but no megaloblastic change. The mortality was at least 38 per cent. Adequate diet control of infection and transfusions were the most effective therapeutic measures but even with these recovery was slow. Eighteen of 36 patients given liver injections showed a response which was possibly attributable to the liver but the general impression was that the anemia was not strikingly influenced by liver or yeast extracts.

Knowledge of the tropical macrocytic anemias is clearly far from complete. This group of cases does not seem to conform to the anemia described by Wills. The etiology is complex and the author suggests that long-standing nutritional defects and repeated malarial infections antedating military service were of prime etiologic importance.

S C

**OBSERVATIONS ON RELAPSES IN PERNICIOUS ANEMIA** *E Jones C C Tillman and W J Darby* From the Vanderbilt University Hospital Nashville Tenn *Ann Int Med* 30 374-380 1949

Liver extract was discontinued on 12 patients with pernicious anemia. Red count hemoglobin and determinations of fecal urobilinogen were made. Relapse was defined as a fall in red count on two successive measurements to more than two standard deviations below the average red count of the patient's during treatment. Six of the 12 patients failed to show hematologic relapse over a period of twenty six to twenty nine months. Eight to eighteen months were required to produce relapse in these patients. Of interest was the increase in urobilinogen above 350 Ehrlich units in some cases when the red count fell to between 2.5 and 3.5 million.

**INCIDENCE OF THE BLOOD GROUPS AND THE SECRETOR FACTOR IN PATIENTS WITH PERNICIOUS ANEMIA AND STOMACH CARCINOMA** *R P Ladenson S O Schwartz and A C Ivy* From the Hematology Laboratory and the Hektoen Institute for Medical Research of the Cook County Hospital and the Department of Clinical Research of the University of Illinois Chicago Illinois *Am J M Sc* 217 194-197 1949

This survey of the incidence of the blood groups (O A A<sub>1</sub> A<sub>2</sub> B AB A<sub>1</sub>B A B M N MN Rh<sub>+</sub> and Rh<sub>0</sub> negative) as well as the secretor and nonsecretor (gastric) attributes was undertaken in the attempt to determine whether any relationship existed between them and pernicious anemia and stomach carcinoma. No relationship was found between pernicious anemia and the blood groups or Rh negative oess. Patients with pernicious anemia secrete blood group specific substances in their saliva in the same proportion as normal individuals. The percentage of secretors and nonsecretors was approximately the same in pernicious anemia patients who showed gastric atrophy as it was in those who had a normal gastric mucosa. Patients with carcinoma of the stomach show an approximately normal distribution of blood groups and the secretor trait.

THE TREATMENT OF SUBACUTE COMBINED DEGENERATION OF THE SPINAL CORD WITH VITAMIN B<sub>12</sub> T D Spies R E Stone S Karlus and T Aramburu From the Department of Nutrition and Metabolism Northwestern University at Hillman Hospital Birmingham Alabama South M. J. 41 1030-1031 1948

Three patients with pernicious anemia and acute neurologic manifestations of posterolateral sclerosis were treated with vitamin B<sub>12</sub>. Typically 25 micrograms of the material was given by injection every forty-eight hours for four injections. In all patients there was a rapid subjective and objective improvement beginning within two to five days after start of therapy.

S.E.

TENTATIVE APPRAISAL OF VITAMIN B<sub>12</sub> AS A THERAPEUTIC AGENT T D Spies R M Suarez, G G Lopez F Milanes R E Stone R L Toca T Aramburu and S Karlus From the Department of Nutrition and Metabolism Northwestern University at the Hillman Hospital Birmingham Alabama and at Calixto Garcia Hospital Habana Cuba and from School of Tropical Medicine San Juan Puerto Rico J A M A 139 521-525 1949

This clinical article reviews the effect of vitamin B<sub>12</sub> in a group of patients with macrocytic anemia. Four patients had nutritional macrocytic anemia, one had nontropical sprue, 11 had tropical sprue and 5 had pernicious anemia. In addition 14 patients with known pernicious anemia who also had posterolateral sclerosis were studied. It was found that, in all cases, the administration of vitamin B<sub>12</sub> (parenterally) was followed by rapid subjective and objective improvement. In the patients with anemia there was increase in strength, return of appetite, elimination of paresthesiae of the tongue and improvement in the character of the stools (in sprue). Reticulocytosis occurred and was followed by improvement in the levels of red cells, hemoglobin and leukocytes. In the patients with neurologic lesions there was alleviation of tingling, stiffness and numbness and remission of neurologic signs.

Details of dosage and management with B<sub>12</sub> are noted to require individual management in each particular case.

S.E.

EFFECTS OF FOLIC ACID ON THE ANEMIA INDUCED BY X IRRADIATION S P Stearns From the Biology Division of the Argonne National Laboratory Chicago Illinois Proc Soc Exper Biol & Med 89 515 521 1948

Pursuant to previous investigations (J Lab & Clin Med 32 1425 1947 Abst 37) indicating the lack of response to folic acid of the macrocytic anemia produced by the administration of radioactive strontium, the efficacy of this hemopoietic principle was tested in white rats receiving the approximate median lethal dose of total body x irradiation which is presumed to cause damage to viscera as well as to bone marrow. The results indicated that folic acid provided little or no stimulus to erythropoiesis following exposure to x radiation. The authors conclude, therefore, that the resultant bone marrow damage was attributable to direct injury and that irradiation damage to viscera involved in the elaboration of the anemia principle must have played a relatively unimportant role in the production of anemia.

C.P.E.

DIETARY EFFECTS ON ANEMIA PLUS HYPOPROTEINEMIA IN DOGS F S Robbert Robbins and G H Whitely From the Department of Pathology the University of Rochester School of Medicine and Dentistry Rochester New York J Exper Med 89 339-368 1949

In order to study the production of hemoglobin and plasma protein by various specific food proteins dogs were first depleted of hemoglobin and plasma proteins by frequent blood removal and a nonprotein diet containing all other dietary essentials

I Some Proteins Further the Production of Hemoglobin and Others Plasma Protein Production (pp 339-358)

Although there was a satisfactory production of total blood protein with the various egg fractions fresh and processed fresh and processed meat fresh beef heart and canned salmon muscle, certain quantitative and qualitative differences were noted. In general a meat diet produced a greater amount of new blood protein than did the several egg products. Also on a meat diet the hemoglobin production greatly exceeded the plasma protein production whereas the egg protein diets favored the production of plasma proteins. More specifically the hemoglobin production with fresh beef muscle was three or four times that of plasma protein and the output of total blood protein with fresh or processed beef muscle twice that obtained with the egg diets. Beef heart and salmon muscle produced a pattern similar to beef muscle except that the total blood protein output was less. Processed egg albumin was the only egg product not well utilized.

II The Findings with Milk Products Wheat and Peanut Flours as Compared with Liver (pp 359-368)

Liver was used as a control in these experiments as it gives maximum amounts of newly formed blood protein with a hemoglobin production of approximately three times that of plasma protein. Casein was found to compare favorably with liver and meat. Lactalbumin was not as effective as casein but like the egg proteins it favored plasma protein production. Peanut flour gave a poor response. While the response to wheat gluten was better than that with peanut flour its unpalatableness presented difficulties in experimental control.

These two papers are an extension of previously reported studies on body and blood proteins. Further work on this subject is being carried out with radioactive isotopes to determine more accurately the exchange which can take place between body and circulating proteins in protein-depleted dogs.

H B M

THE EFFECTS OF SULFONAMIDES ON AMBLYSTOMA EMBRYOS WITH PARTICULAR REFERENCE TO BLOOD DEVELOPMENT *W. M. Copenhaber and S. R. Detweiler* From the Department of Anatomy College of Physicians and Surgeons Columbia University, New York N. Y. *J. Exper. Zool.* 109 239-257 1948

Sulfonamides have been used successfully in reducing mortality rates following surgical procedures on Amblystoma embryos. Since some animals showed toxic effects the present investigation was undertaken to study the effect of different concentrations of sulfadiazine and sulfanilamide on embryos at the blastula, gastrula and tail bud stage of development. The range of drug concentration in spring water was 0.12 to 2.0 per cent. Anemia was more frequent and more pronounced in sulfanilamide treated animals. Splenic development was markedly suppressed. Granulopoiesis in the subcapsular region of the liver was apparently unaffected. The anemia seemed to be a combination of aplastic and hemolytic types. Because of the hematologic response of these animals they may be useful for testing the effects of other drugs.

O P J

FACTORS INFLUENCING THE BLOOD PICTURE OF THE NEWBORN. STUDIES ON SINUS BLOOD ON THE FIRST AND THIRD DAYS *Q. B. DeMarsh, H. L. Alt and W. F. Windle* From the Department of Medicine and Anatomy Northwestern University Medical School and the Cook County Hospital Chicago Ill. *Am. J. Dis. Child.* 75 860-871 1948

In order to determine the factors which may influence the blood picture in the newborn and which have mainly accounted for the present lack of standard blood values the authors studied the effects of early and late clamping of the umbilical cord by heel punctures and blood volume determinations (see *J. A. M. A.* 116 2568 1941 and *Am. J. Dis. Child.* 63 1123 1942) and in the present report by observations on sinus blood.

The most important cause of variation in blood values is the time of clamping of the cord after delivery. When clamping is delayed until the placenta has separated approximately 108 cc of placental blood otherwise lost by immediate cord clamping is added to the infant's circulation, a rapid adjustment of plasma volume occurs, and the infant's blood volume is increased by the volume of these additional

red cells. Significantly higher values for hemoglobin, red cell count and hematocrit were obtained when clamping was delayed. For example, the mean value of hemoglobin in sinus blood on the first day was 20.6 Gm per cent compared to 16.4 Gm per cent when the cord was clamped immediately on delivery.

Other variable factors were the source of blood (blood levels were higher with capillary than with sinus blood) and, of less significance, the time after birth at which the blood sample was taken.

That increased erythropoiesis is prolonged, probably as a compensatory mechanism, in the group deprived of the additional placental blood was indicated by a comparison of the reticulocyte counts made on the third day in the two groups.

H.B.M.

## ERYTHROCYTE FRAGILITY

AN IMPROVED METHOD FOR THE DETECTION OF OSMOTIC ABNORMALITIES OF ERYTHROCYTES. *M. H. Jaishankar, D. R. Stewart, W. J. Brown and L. J. Kammelman*. From the Department of Physiology, University of Pennsylvania School of Medicine, Philadelphia, Pa. *Am. J. M. Sc.* 217: 47-52, 1949.

In order to avoid certain sources of error in the usual clinical fragility test with hypotonic salt solutions, as well as to shorten the time and reduce the number of solutions required for a test, an alternative procedure is suggested in which a continuous hemolysis curve is obtained, either with or without photographic recording, in a solution containing a penetrating solute such as thionin or glycerol.

Using this method the hemolysis curves are similar to those obtained with hypotonic salt solutions, but small individual peculiarities are brought out.

G.E.C.

THE OSMOTIC RESISTANCE OF HUMAN ERYTHROCYTES IN NORMAL, CARRIER AND ANEMIC STATES WITH SPECIAL REFERENCE TO CHANGES DUE TO AGE, RACE, SICKLE-CELL ANEMIA, MEDITERRANEAN (COOLBY) ANEMIA AND CONGENITAL HEMOLYTIC ICTERUS. *B. Dickstein, W. E. Landmesser, Jr., W. E. Lee, T. H. Wilson and I. J. Wolman*. From the Children's Hospital of Philadelphia and the Departments of Pediatrics and Physiology, University of Pennsylvania School of Medicine, Philadelphia, Pa. *Am. J. M. Sc.* 217: 53-61, 1949.

Utilizing a reproducible method, photographic records of the hemolysis of erythrocytes from 170 normal persons and 90 anemic individuals have been obtained. In white subjects the osmotic resistance of the erythrocytes in the 0 to 10 year age group was found to be greater than that of normal adults. A comparable age difference was not found in a limited number of Negroes. The average osmotic resistance of the erythrocytes of the normal Negro was greater than that of the normal white in the corresponding age group. The erythrocytes of children with sickle cell anemia were more resistant than those of normal Negro children. The average for individuals with the sickle cell trait was between that for sickle cell anemia and that for the normal, but with considerable overlapping in both directions. In both Mediterranean anemia and its carrier state the blood was markedly more resistant than that of the normal controls, the carrier showing a resistance as great as that of the anemic individual.

G.E.C.

THE TONICITY VOLUME RELATIONS FOR SYSTEMS CONTAINING HUMAN RED CELLS AND THE CHLORIDES OF MONOVALENT CATIONS. *E. Pender*. From The Nassau Hospital, Mineola, Long Island, N. Y. *J. Gen. Physiol.* 32: 391-398, 1949.

It has been known that when red cells are suspended in solutions of different ionic composition but of the same depression of the freezing point, that there are discrepancies in the relation between tonicity and volume. Chlorides of monovalent cations obtained from two different sources were prepared in a 0.172 M solution in water. The salts used were LiCl, NaCl, KCl, RbCl and CsCl. Red cells were most fragile in LiCl and least fragile in NaCl. The  $K^+$  losses in LiCl were so small and slow that they could not be counted for the increased fragility. It has been pointed out that there are differences in the molarity of solutions which are isotonic with plasma.

O.P.J.

THE TONICITY VOLUME RELATIONS FOR HUMAN RED CELLS SUBJECTED TO THE ACTION OF HEAT WITH SPECIAL REFERENCE TO PROLYTIC K LOSS. *E. Ponder* From The Navan Hospital, Min-ola, Long Island N. Y. *J. Gen. Physiol.* 3: 399-405, 1949.

It has been thought that heating red cells for short periods between 49.6°C and 50.6°C had small effect on the swelling which occurs in hypotonic media of different tonicity. Suspensions of washed red cells in NaCl were heated for two minutes at 45°C and 50°C and then allowed to cool to 25°C. After an hour at this temperature, samples were obtained for the determination of cell volume and the extent of hemolysis. At 45°C, heated and unheated cells behave equally well as osmometers, but those heated at 50°C have an impaired ability to swell in hypotonic solutions. Heated cells lyse in higher tonicities than unheated ones. Some of these findings may be accounted for by the large K losses and K-Na exchange. O.P.J.

## IMMUNOHEMATOLOGY AND TRANSFUSION

ANÉMIE HÉMOLYTIQUE AIGUE ÉRYTHROBLASTIQUE TRÈS TARDIVE (VERY LATE ACUTE ERYTHROBLASTIC HEMOLYTIC ANEMIA). *M. Kaplan, M. Bessis, F. Barratt, P. Dilhailar, J. C. Caine*. *Arch. Franç. Ped.* 5, No. 6, 1948.

The third child of a family with an Rh negative mother and Rh positive father was affected by a hemolytic anemia which did not appear until the seventh week after birth. Antibodies were found at the examination 25 days after delivery (1:1 in saline, 1:8 in albumin medium). The Coombs test was positive.

The second child had had a similar anemia when he was 6 weeks old, probably of the same nature.

Between the first and the second pregnancy, the mother received a transfusion with Rh positive blood which may have increased her iso-immunization.

The child was fed with cow milk, and thus the maternal antibodies could not have been given by any other route than the transplacental. It is difficult to decide whether the maternal antibodies fixed themselves on the infant red cells a long time after birth, or whether they were fixed early and destroyed the cells only after a long interval.

The very severe anemia of this third child was treated with Rh positive transfusions, which was believed to be preferable to Rh negative blood, since there were no more maternal antibodies in the infant's circulation at this time.

J.P.S.

USE OF BLOOD DONORS WITH POSITIVE SEROLOGIC TESTS FOR SYPHILIS WITH A NOTE ON THE DISAPPEARANCE OF PASSIVELY TRANSFERRED REAGIN. *M. M. Raistch, T. W. Farmer, and B. Davis*. From the Departments of Surgery and Medicine, the Johns Hopkins University and Hospital, Baltimore, Md. *J. Clin. Investigation* 28: 18-23, 1949.

Sixteen patients with negative serologic tests for syphilis were studied after receiving injections of plasma from blood donors with positive STS. The period of storage before separation of plasma from the luteal donor bloods varied from one to ten days, and the intervals between freezing and thawing of the plasma ranged from two weeks to two months. In all instances a positive STS was acquired by the recipient; the initial titer of which represented the dilution to the recipient's blood volume of the reagent contained in the injected plasma. Reversion of the tests to negative occurred in all instances within a period of 20 days. It is concluded that the blood of donors with syphilis should be acceptable for use in any blood bank with a plasma program, inasmuch as infectivity of the material is abolished by freezing or by storage for a minimum of four days in the refrigerator.

C.P.E.

THE VERY RARE RH GENOTYPE  $R_{YK}$  (CoE/CdE) IN A CASE OF ERYTHROBLASTOSIS FOETALIS. *C. van den Bosch*. From the Department of Pathology, University of Louvain, Belgium. *Nature* London 162: 781, 1948.

In a case of erythroblastosis foetalis, the mother's blood group was O(MNP) and the cells were agglutinated by anti-C, anti-E but not by anti-D. Her serum contained complete and incomplete anti-D. She thus belonged to the very rare allelic combination CdE (Wiener's  $r_{YK}$ ) predicted by Fisher in 1944.

Detailed study of the family made it possible to identify CdE as an inherited combination on one chromosome. This discovery brings additional support to Fisher's already very well founded theory. STC.

**A HEMOLYSIN ASSOCIATED WITH THE MUMPS VIRUS** *H R Morgan, J F Enders and P F Wagley* From the Research Division of Infectious Diseases of the Children's Hospital, Children's Medical Center and the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard) Boston City Hospital, Harvard Medical School, Boston, Massachusetts. *J. Exper. Med.* **81**: 503-514, 1948.

The observations made on an hemolysin found in the amniotic and allantoic fluids of chick embryos infected with the virus of mumps are presented. Chicken, sheep and human erythrocytes were all susceptible to hemolysis although those of man were less affected.

It appears evident from the following observations that this hemolytic activity is due to a specific product of the mumps virus: (1) a similar hemolysin could not be demonstrated in normal egg fluids or in those infected with two strains of influenza virus; and (2) the hemolysin could be inhibited by mumps convalescent sera from man and monkey but only slightly by normal monkey serum taken during the early stage of the disease in man.

The authors have inferred from their study of the effect of heat, temperature and time of incubation and of pH on the hemolysin that this hemolytic activity is not identical with the hemagglutinative property of the infected fluid. That some as yet undefined relationship exists between these two factors, however, is indicated by the similarity of their behavior in respect to adsorption on and elution from chicken red blood cells and their inhibition by specific immune serum. Attention is also drawn to the enzyme-like behavior of the hemolysin.

**HEMOLYTIC ANEMIA ASSOCIATED WITH ATYPICAL HEMAGGLUTININS** *W. J. Kabus and P. F. Wagley* From the Department of Medicine, School of Medicine, Johns Hopkins University and Baltimore Rh Typing Laboratory, Baltimore, Md. *Ann. Int. Med.* **30**: 408-423, 1949.

A very interesting case is reported showing intravascular thrombosis and atypical hemagglutinins in high titer. In addition to cold hemagglutination, a warm hemagglutinin was demonstrated which reacted at 37 degrees with the patient's cells and with 63 per cent of bloods compatible for  $A_1$ ,  $A_2$ ,  $O$ ,  $M$ ,  $N$ ,  $Rh$  and  $Hr$ . The nature of these agglutinins and their possible role in hemolytic anemia and intravascular thromboses are discussed in competent and interesting fashion.

C.A.F.

**CLINICAL USE OF BLOOD DERIVATIVES** *C. A. Janeway* From the Department of Pediatrics, Harvard Medical School and the Children's Medical Center, Boston, Massachusetts. *J. A. M. A.* **138**: 859-865, 1948.

This survey of the field of blood derivatives summarizes the advances of therapeutic knowledge of these substances especially during the past ten years. In brief, the following points are covered:

1. **Blood Cells** White cells and platelets can as yet not be satisfactorily separated and preserved; red cells can. Red cells resuspended in saline to a hematocrit of 65 per cent constitute an ideal treatment for certain patients with anemia, for (a) it is possible thus to supply more hemoglobin with less loading of the circulation, and (b) the removed plasma may be reserved for use for other patients. Hemoglobin itself has been prepared from red cell fractions for possible use in traumatic shock; experimentally, its high oxygen-carrying capacity combined with its high osmotic activity make it theoretically excellent for shock treatment, but actually the injection of pure hemoglobin is often followed by depression of renal function, so that its clinical use has had to be cautious to the extreme. Globin itself may be used as a substitute for plasma proteins.

2. **Plasma** Whole plasma is, of course, used widely in the treatment of shock. The occurrence of homologous serum hepatitis after the administration of plasma, however, has been a drawback. Statistics are presented as to the incidence of this disorder under various conditions; single transfusion of blood

or serum (hepatitis rare) use of fraction I from pooled plasma (hepatitis in 10 per cent of subjects) use of pooled plasma or serum (hepatitis in 4 to 7 per cent of recipients) Methods of preventing this hepatitis are mentioned of these only sterilization of the plasma seems potentially practicable The author suggests the use of pooled plasma only if neither blood nor serum albumin are available

3 Plasma Fractions Discussed are *factors important in coagulation* (fibrin, thrombin fibrinogen anti hemophilic globulin) *blood grouping globulins disease antibodies* (gamma globulin for measles hepatitis, mumps) and *albumin* All these substances have already found widespread clinical use for their particular qualities

The article is not meant to be all inclusive but covers the salient material in a brief salient manner

## IRON METABOLISM

CHEMICAL CLINICAL AND IMMUNOLOGICAL STUDIES ON THE PRODUCTS OF HUMAN PLASMA FRACTIONATION

XXXIX THE ANEMIA OF INFECTION STUDIES ON THE IRON BINDING CAPACITY OF SERUM *G E Carlwright and M M Wintrobe* From the Department of Medicine, University of Utah School of Medicine Salt Lake City Utah J Clin Investigation 28 86-98 1949

From determinations of the serum iron concentrations and unsaturated iron binding capacity of serum from which the total iron binding capacity and per cent of iron saturation of serum were calculated, the authors conclude that the hypoferrernia accompanying infections is not the result of a reduction in the iron binding capacity of serum but must depend upon some other factor The total iron binding capacity of serum in 30 normal individuals averaged approximately 360 gamma per cent the iron binding protein being approximately 35 ( $\pm 6$ ) per cent saturated with iron In 13 patients with chronic infection in 2 dogs with sterile abscesses and another with an acute infection the total iron binding capacity was significantly reduced but the reduction in serum iron was proportionately greater, with the result that the per cent saturation was lowered

Measurements of serum iron concentration following intravenous iron injections indicated that the concentration peaks were limited by the capacity of the serum to bind iron, and when the total iron binding capacity of the serum was exceeded the unbound iron rapidly left the blood stream with the concomitant development of toxic symptoms The administration of metal-combining globulin (fraction IV 7) to 2 patients with chronic infection resulted in a temporary increase to normal in the total serum iron binding capacity Subsequent intravenous injections of iron resulted in a greater initial five minute rise in the serum iron concentration than had previously been noted but the rate of iron disappearance from the serum was not significantly affected Moreover, the temporary artificial increase in iron binding capacity was not followed by a detectable mobilization of iron in the blood

C P E

CHEMICAL CLINICAL AND IMMUNOLOGICAL STUDIES ON THE PRODUCTS OF HUMAN PLASMA FRACTIONATION

XXXVIII SERUM IRON TRANSPORT MEASUREMENT OF IRON BINDING CAPACITY OF SERUM IN MAN *C E Rath and C A Finch* From the Department of Medicine Harvard Medical School and the Medical Clinic Peter Bent Brigham Hospital Boston Mass J Clin Investigation 28 79-85 1949

A protein constituent of plasma a beta 1 globulin with the capacity to bind metal ions particularly iron copper and zinc (Science 104 340 1946) has been measured in normal and pathologic sera by these authors who performed concomitant measurements of the serum iron concentration and computed the unsaturated iron binding capacity as well as total iron binding capacity of these sera In a group of 30 normal subjects the serum iron concentration averaged 100 gamma iron binding capacity 200 gamma and total capacity 300 gamma per 100 cc of serum the circulating iron binding protein was on the average 34 per cent saturated with iron

In cases of iron deficiency whereas the serum iron concentration was lowered both the unsaturated iron binding capacity and the total iron carrying capacity of the serum were elevated In the presence of infection not only the serum iron but also the iron-binding capacity and total capacity were reduced In a variety of debilitating conditions with associated hypoproteinemia there was a reduction in the iron binding capacity of the serum and no elevation of the latter was observed even when iron deficiency was present as an additional complication No deviation from the normal was found in pregnant women Elevated values for serum iron and percentage saturation of the iron binding protein were found in refractory anemia, pernicious anemia hemochromatosis transfusion hemosiderosis and liver disease

Human plasma fraction IV- $\gamma$  binding iron in the proportion of 1 ml per ml of prot in was injected intravenously into 22 individuals in amounts of 2.5-5.0 grams the injection times ranging from 15 to 30 minutes. The injections which were without incident were followed by a rise in serum iron which reached a peak 12 to 24 hours after injection and subsided over a period of 2 to 6 days excepting in cases of hemosiderosis and hemochromatosis in whom a more sustained elevation occurred.

The evidence indicated that the body iron is completely protein-bound which perhaps explains the lack of a physiologic mechanism for iron excretion. Excepting in terminal hemochromatotic patients in whom some of the excessive serum iron is apparently bound to other proteins, the serum iron is found exclusively in combination with the beta<sub>2</sub> globulin designated as the iron binding protein (J Clin Investigation 28: 73, 1949). The elevations in iron binding protein observed in cases of iron deficiency may be responsible for the enhanced iron absorption in this condition, but the relation of iron-binding capacity to the facility and rate of iron absorption remains to be established. The finding of increased iron saturation implying the co-existence of bone marrow block, iron excess and severe liver disease is of great value in the differential diagnosis of hemochromatosis and simple cirrhosis.

CPE.

A STUDY OF HISTOCHEMICAL IRON USING TRACER METHODS. Y. M. Endicott, T. Gillman, G. Breiter, A. T. Ness, F. A. Clarke and E. P. Adamik. From the Pathology Laboratory, Experimental Biology and Medicine Institute, National Institutes of Health, Bethesda, Md. J. Lab. & Clin. Med. 34: 414, 1949.

Combined histochemical, radioautographic and tracer methods were used to study the absorption and distribution of single test meals of radioiron in guinea pigs, rats and one dog. The iron demonstrated histochemically in the duodenal mucosa, the mesenteric and cervical lymph nodes, liver and spleen was derived largely from sources other than the single test meal. This visible iron did not undergo well defined cyclic changes after a single test meal. It accumulated over a period of days or weeks of continued intake of a diet containing considerable iron. It behaved more like storage iron than iron in transport. The visible granular iron in the duodenal epithelium exerted no demonstrable effect on the amount of iron absorbed, and it did not appear to be a morphologic expression of mucosal block. Most of the radioiron of the test meal traversed the duodenal epithelium rapidly. In one dog it was transported from the intestine via the portal vein, only insignificant amounts being found in the thoracic duct lymph. There was no evidence to indicate that the reticulo-endothelial system participated directly in the absorption of iron from the intestine or transport of the absorbed iron from the intestine to the liver, blood and other organs and tissues.

## POLYCYTHEMIA VERA

BLOOD OXYGEN STUDIES IN PATIENTS WITH POLYCYTHEMIA AND IN NORMAL SUBJECTS. L. P. Wasserman, R. L. Dobson and J. H. Laurence. From the Division of Medical Physics and Division of Medicine, University of California, Berkeley, Calif. J. Clin. Investigation 28: 60-65, 1949.

Determinations of the arterial blood oxygen saturation were made in 74 individuals of whom 48 were cases of polycythemia vera. The data presented indicated that the degree of arterial oxygen saturation was within the limits of normal in resting polycythemic subjects, normal values being found in patients with hematocrits as high as 81 per cent. The authors suggest that low oxygen saturation figures reported in the literature may have been attributable to technical errors inherent in gasometric measurements, which may have resulted from failure to conduct tests promptly after the blood samples were obtained. The erroneously low oxygen saturation values may depend on the fact that inactive hemoglobin (J. Biol. Chem. 138: 563, 1941) as well as carboxyhemoglobin are converted in vitro to normal reactive hemoglobin with resultant increase in the apparent oxygen capacity.

CPE.

## LEUKOCYTES

PRIMARY SPLENIC NEUTROPENIA. M. S. Sacks and T. N. Carey. From the Department of Medicine, University of Maryland School of Medicine and College of Physicians and Surgeons, Baltimore. South. M. J. 41: 922-925, 1948.

This is a case presentation of a 56 year old woman who at the age of 55 developed fatigue followed by otitis followed by furunculosis. Examination revealed hepatosplenomegaly. There was a slight anemia but the striking finding in the blood was a leukopenia (1100) with granulocytopenia (19 per cent neutrophils). The bone marrow was somewhat hypocellular and was considered to show decreased number of granulocytes with a shift to the left. Ultimately splenectomy was undertaken. The spleen weighed 2,200 grams and showed congestion. Following operation the white count rose to normal levels (e.g. 10,700) with normal granulocyte counts (e.g. 69 per cent). The blood count remained normal during the following two years when the patient died of pulmonary atelectasis and apparent hepatic disease. The liver at autopsy showed congestion.

Unfortunately meager data are presented and the exact mechanisms of neutropenia cannot easily be interpreted. It seems likely however that the case is one of the generic hypersplenic neutropenia group relieved by splenectomy.

S E

**PRIMARY SPLENIC NEUTROPENIA. A SPECIFIC INDICATION FOR SPLENECTOMY.** L. T. Palumbo. From the Department of Surgery, Veterans Administration Hospital, Des Moines, Iowa. *Ann Surg* 129: 131-136, 1949.

A patient with a marked leukopenia (2,500 per cu. mm.) marked splenomegaly without anemia or thrombocytopenia was splenectomized with complete alleviation of the leukopenia. This patient was followed 56 days postoperatively. No specific pathology was found in the spleen. The bone marrow as determined by sternal puncture was cellular. The author concludes that this was a case of primary splenic neutropenia and that the disease results from splenic dysfunction as a result of selective destructive action of the reticulo-endothelial cells of the spleen. It is to be regretted that this patient was followed for such a short period of time.

G E C

**CHRONIC CYCLICAL GRANULOPENIA.** B. Barling. *Proc Roy Soc Med* 41: 653-4, 1948.

This note discusses the occurrence over a period of twenty years of periodic ulceration of the mucous membranes in association with leukopenia and neutropenia. The patient, a woman, developed recurrent ulcers of the tongue, mucosa of the cheek and skin of the angles of the mouth approximately every four weeks from the age of 12 on. During pregnancy at the age of 30 additional lesions at the vulva occurred. At the age of 31 ulcers developed also at the lower leg and resisted healing.

Physical examination except for the ulcerations and their scars was regularly negative. Spleen, liver and lymph nodes were not palpable. The red cell count, hemoglobin and sternal marrow punctures were normal. The persistent abnormality was leukopenia which was due to neutropenia. Typical counts ranged from a total white count of 1,300 to 4,800 with granulocytes from 300 to 3,000 per cu. mm. (normally granulocytes range 3,000 to 6,000 per cu. mm.). Treatment with liver, hog's stomach, nicotinic acid, pyridoxin, pentanucleotide, nucleic acid, yellow bone marrow extract and iron had no effects either on the blood count or the lesions.

The etiology for this type of abnormality has never been explained. The ulcerations are considered the result of lowered resistance due to granulocytopenia. Treatment is universally ineffective. (See H. A. Reimann, *J. A. M. A.* 136: 238-244, 1948.)

S E

**CHRONIC GRANULOPENIA.** B. Barling. *Proc Roy Soc Med* 41: 654-5, 1948.

This case report concerns chronic neutropenia associated with splenomegaly in a 17 year old girl. These abnormalities were first discovered at the age of 15 during the course of investigation of an acute gastroenteritis. In the following six months she required hospitalization for persistent and recurrent fever, pallor and infections including a severe bout of pneumonia. The positive physical findings included a just palpable liver and an easily palpable spleen; there was no lymphadenopathy. Anemia was present (R.B.C. 1.54 million, hemoglobin 25 per cent), platelets were normal and the white count was low (e.g. 3,200 with 11 per cent granulocytes). A bone marrow puncture was normal.

After blood transfusion and recovery from pneumonia the patient remained in good health and developed normally. The spleen however continued to increase steadily in size and the white count and granulocyte count were regularly low. The question of splenectomy was tabled because of a negative adrenalin test.

This case of course is different from the cyclic neutropenia without anemia and without splenomegaly.

described by Barling (Proc Roy Soc Med 41 633-4 1948 see preceding abstract) and others and perhaps corresponds better to splenic neutropenia or splenic neutropenia with anemia (Doan and Wiseman, Dameshek) in which splenectomy may be expected to give beneficial results

SE

**MECHANISMS OF LEUKOPENIA WITH INFLAMMATION. AN ADDITIONAL LEUKOPENIC FACTOR FOUND IN ALKALINE EXUDATES.** V Menkin. From Chase Foundation for Cancer Research Temple University School of Medicine Philadelphia Pa Arch Path 46 145-158 1948

Exudative material withdrawn from the pleural cavities of dogs injected with turpentine are usually alkaline and they contain an extractable leukocytosis promoting substance. When this material is allowed to age for several months some of its properties change by becoming insoluble in isotonic saline. The leukocytosis-promoting substance is in the supernatant while a leukopenic component is in the insoluble residue. This leukopenic component differs from the one found in acid exudates by being inactivated by incomplete hydrolysis with tenth normal hydrochloric acid. However it appears that both of these factors exist in combination in fresh exudates and therefore help to explain the mechanism of leukopenia with inflammation.

OPJ

**DESTIN DES GRANULOCYTES TRANSFUSÉS (FATE OF TRANSFUSED GRANULOCYTES)** Bernard Dreyfus Sang 19 570-574 1948

A transfusion of 600 cc of myeloid leukemic blood containing 250 000 granulocytes by cubic millimeter was done in each of two recipients affected with subacute hemocytoblastic and lymphoblastic leukemias.

In both the increase was very short and the survival of the white cells was under 30 minutes. The blood examination shows in this initial period many forms of destruction. Thus the cell's destruction seems to be intravascular and not intracellular as has been said. The lysed cells also disappear very quickly from the blood stream and this explains the difficulty encountered in observing the phenomenon.

The total white cell count was lower 2 hours and 24 hours after the transfusion than it was before (31 500 against 50 000 in the first case 41 400 against 52 000 in the second case). This suggests that some of the white cells of the recipient are destroyed in the first hours following transfusion.

These results are to be compared with those of Minor and Isaacs (1925) who found a similar reduction of the injected white cells injecting lymphoid leukemic cells to a patient with lymphosarcoma but injecting only 450 cc of blood containing 89 200 white cells per cubic millimeter. They found a very slight modification in the white count and they did not find any lysed cells.

Dreyfus's conclusions are that no substitutive effect is to be found for white cells in blood transfusion, and that all increase in white cell count found after blood transfusion expresses only the regeneration capacity of the recipient.

JPS

**A MACROPHAGE PROMOTING-FACTOR (MPF) IN THE BLOOD OF RABBITS.** C M Pomeroy W Jacobson and M F Orr. From the Department of Anatomy University of Texas Medical Branch Galveston Texas Am J Anat 84 1-19 1949

When embryonic chick spleen fragments were implanted it was observed that in some instances cultures containing 25 per cent normal rabbit serum would produce great numbers of phagocytic cells which ingested myelocyte debris. Experiments were undertaken to determine the occurrence and nature of this macrophage promoting factor (MPF). Control hanging drop preparations were grown in a medium of 50 per cent fowl plasma 25 per cent embryonic juice and 25 per cent Tyrode's solution. In the test preparations heterologous sera or resuspended fractions of sera were substituted for the Tyrode component. In cultures containing MPF the area of outwandering cells was markedly reduced, myelocytes were not at the periphery and many macrophages were at the peripheral zone. This factor was not present in all animals and it even varied within a given animal over a period of months. Oddly enough MPF was present only in the species known to have the Forssman antigen. Properties of the MPF are: it is thermostable and resists freezing-drying; it is insoluble in absolute alcohol or acetone but soluble in Tyrode after precipitation in 1/3 saturated ammonium sulfate. It does not seem to be identical with any of the factors in inflammatory exudates as reported by Menkin.

## BLOOD COAGULATION

PROTHROMBIN CONVERSION FACTOR OF DICUMAROL PLASMA *C A Owen and J L Bollman* From the Division of Experimental Medicine, Mayo Foundation, Rochester Minnesota Proc Soc Exp Biol & Med 67 231-234 1948

Data obtained from experiments on dicumarolized dogs suggests that the hemorrhagic diathesis produced by dicumarol is attributable not alone to a disappearance of prothrombin but also to the loss of a factor, the function of which is to facilitate the conversion of prothrombin to thrombin. Variations in the concentration of this conversion factor present in plasma serum, or serum pseudo-globulin may explain the familiar discrepancies in the results of one and two-stage methods of estimating prothrombin activity. It may also account for the therapeutic efficacy of serum in the treatment of cattle with sweet clover disease, a phenomenon otherwise difficult to explain.

C P E

ACTION DE LA PHENYL INDANE DIONE SUR LE TAUX DE LA PROTHROMBINE I ETUDE EXPERIMENTALE SUR LE LAPIN *J P Soulier and J Guiguen* II UTILISATION EN CLINIQUE HUMAINE. (EFFECT OF PHENYL INDANE DIONE ON PROTHROMBIN LEVELS I EXPERIMENTAL STUDIES ON THE RABBIT II USE ON HUMANS) *J Guiguen and J P Soulier* Rev Hemat 3 180-195 1948

In the first series of experiments using 16 rabbits the authors found that phenyl indane-dione (PID) had a very marked effect on prothrombin level. Doses of 10 to 20 milligrams per kilo produced a decrease of prothrombin to a level of 30 to 40 per cent this effect being reached before the eighteenth hour. There was no modification of platelets clot retraction or fibrinogen level. Higher dosage did not produce greater hypoprothrombinemia and the authors did not find any hemorrhages even with a dosage ten times the standard dosage. The lethal dose was well over 600 mg/kilo which gave a very high safety margin. Histologic examinations of the rabbits given very high doses of PID (under 400 mg/kilo) did not show histologic injuries.

The PID was used in the prevention of thrombosis in 43 women after pregnancy. In all these cases doses of 10 to 20 mg/kilo yielded a very constant decrease of prothrombin level. The decrease began earlier than with dicumarol about the twelfth hour and the full effect was obtained between the twenty-fourth and the forty-eighth hour which is a 30 to 40 per cent level. Return to a normal level was quite constant and 100 per cent prothrombin was reached by about the ninety-sixth hour.

This constancy in the chronology is very different from that observed with dicumarol. Individual susceptibility to the drug seems also to be less important than in the case of dicumarol.

In 2 cases the PID was given to patients with known thrombophlebitis (every 3 days 10 mg/kilo). This dose was effective in controlling the prothrombin level around 30 per cent. The patients' state was, in both cases favorably affected. In the 41 cases where the drug was given prophylactically no phlebitis was observed.

In contrast with these advantages the complete inactivity of vitamin K<sub>3</sub> even in huge doses and even when given prior to the administration of the PID must be emphasized. But this fact is perhaps of minor importance since in no case was hemorrhage or hypoprothrombinemia of less than 10 per cent observed.

## LEUKOCYTES, LEUKEMIA AND LYMPHOMA

LA PLASMOCYTOSE CANCÉREUSE (THE PLASMA CELL REACTION OF CANCER) *G Marchal and L Mallet* Sang 19 457 1948

Myelocytosis eosinophilia megakaryocytosis are common bone marrow reactions in case of carcinoma bone metastasis. Erythroblastosis is most significant but plasmacytosis is according to the authors the prominent feature. Rohr and Hegglin Nordenson and above all Stöger discussed this relation. Marchal and Mallet found between 3 and 6 per cent of plasmacytes in more than half the cases of carcinoma bone metastasis and often this moderate plasmacytosis was useful to detect micrometastasis lost in the bone marrow and even in some cases permitted discovery of a latent carcinoma of the lung breast stomach or prostate. The morphology of these plasmacytes is indistinguishable from that of the plasma cells in multiple myeloma. The more or less deep basophilia of the cytoplasm the presence or absence of vacuoles or nuclei are the same, multinucleated cells may be found.

When there are only 4 to 6 per cent plasma cells in the bone marrow the histologic differentiation from myeloma is easy. But it is possible to find more than 10 per cent of plasmacytes in metastatic cancer and in 3 cases of prostatic carcinoma between 25 and 50 per cent of the cells were plasma cells. In such cases differentiation from myeloma is very difficult if aggregates of neoplastic cells are not present in the smear. Moreover hyperproteinemia may be present (13.3 grams per cent in one of the cited cases). In such cases the possibility arises that a true myeloma may exist complicating the metastatic carcinoma.

In addition to involvement of the bone marrow a plasmacytic reaction may be found in the liver and was observed by the authors in a case of metastatic carcinoma of the stomach.

J.P.S.

**CIRRHOSE ATROPHIQUE DU FOIE ET MONONUCLÉOSE INFECTIEUSE (ATROPHIC CIRRHOSIS OF THE LIVER AFTER INFECTIOUS MONONUCLEOSIS)** G. Bukel. *Bull. et Mem. Soc. des Hôp. de Paris* 923-927. Séance 8 Oct. 1948.

It is now well known that atrophic cirrhosis of the liver may follow infectious hepatitis and that hepatitis is a common feature of infectious mononucleosis but we had not found any description of atrophic cirrhosis following infectious mononucleosis so this observation seemed interesting to us.

A 38 year old male was affected in February 1946 with typical infectious mononucleosis (with adenopathy enlarged spleen mononucleosis and a Paul and Bunnell reaction positive at a dilution of 1:16).

Recovery was very slow, and in June jaundice appeared which lasted ten days and which reappeared in September. The liver was now enlarged and ascites appeared. Different hepatic tests were strongly pathological. After aspiration of the ascitic fluid the liver was no longer palpable.

After treatment with transfusions plasma methionine vitamin B and Patek diet the patient improved slowly and following seven months of this treatment was in good health.

This patient had never consumed any alcoholic beverage and the authors believe that the succession of mononucleosis and cirrhosis in this case was not a mere coincidence.

J.P.S.

**THE INTERRELATIONSHIP OF HODGKIN'S DISEASE AND OTHER LYMPHATIC TUMORS** R. P. Carter and W. G. Bernhard. From the Army Institute of Pathology Washington D. C. and the Laboratories of the Presbyterian Hospital in Philadelphia. *Am. J. M. Sc.* 216 625-642, 1948.

The authors studied the histology of 1,300 lymphoid tissues submitted to the Army Institute of Pathology during the past war. Of these 700 cases were Hodgkin's disease. They employed the Jackson-Parker classification and distribution was 14.3 per cent paragranuloma 71.1 per cent granuloma and 14.6 per cent sarcoma. The authors presented illustrations of alterations in histologic composition of lesions and discussed their nature and frequency. A virtually complete alteration in histologic pattern of tumors was noted in 39 per cent of 138 autopsied cases in which biopsies were available. In 384 of 700 cases there were a variety of histologic pictures in different areas.

While classification of lymphoid tumors was useful chiefly from the standpoint of prognosis with the increased therapeutic armamentarium it is of particular importance to correlate the histologic picture with therapeutic response. It may be that the variable nature of the lesion is in part responsible for the inconsistencies in response of this group of neoplasms.

*Malra Di Cooley* By G MAOGIONI AND A ASCENZI Rome Abruzzini Editore 1948 Pp 168

The main part of this monograph is devoted to a detailed report of two severe cases of Cooley's anemia. Though the clinical and laboratory features of the disease are carefully studied, the authors were apparently primarily interested in the anatomic-pathologic findings that are reported in great detail.

The literature was searched particularly for cases with special reference to the general anatomic-pathologic findings (21 cases), gross and microscopic findings of surgically removed spleens (15 cases) and anatomic-histo-pathologic findings of the heart (3 cases).

The pathogenetic views currently held in this country are by and large accepted and confirmed by the authors. Excessive hemolysis is regarded as a constant factor, the concept previously accepted in Italy, of the disease as a chronic erythremic myelosis, is discarded in favor of a hemolytic familial disease. Bone changes are regarded as secondary to myeloid.

This work is primarily useful to those interested in the anatomic-pathologic aspects of Cooley's disease.

DAVIDE LIMENTANI

*Hereditry in Human Leukemia and its Relation to Cancer* By AARV IØERBAEK London England H K LEWIS and Co Ltd 1947 Translated from the Danish (Nyt Nordisk Forlag Arnold Busck Copenhagen) Pp 271 plus 8 pp ref

This book is the English translation of Danish research published in 1947. Of the 279 pages, the first 104 are concerned with methods, analysis and discussion. Almost half of the report presents pedigree charts and case histories of the families and individuals involved. A brief summary in Danish is included and a bibliography is appended.

The analysis of the data in this monograph is based on statistical methods which treat the data on a population (i.e. distribution) basis. Such treatment is both descriptive and evaluative and is effectively used on this material.

This study of leukemia in humans was begun in 1945 at the University Institute of Pathologic Anatomy in Copenhagen, Denmark. Two hundred and nine individuals having leukemia were selected from hospital records available in greater Copenhagen and information was gathered on all immediate members of their families as well as uncles, aunts and grandparents. This leukemic group was then matched as closely as possible by a comparable nonleukemic control group of 200 individuals and the corresponding information of their families.

Information gathered by interview was verified by examination of hospital records and death certificates and it was found that the death certificates of 387 relatives of the leukemic probands showed that one of them had died of any of the diseases inquired about. A similar examination of the death certificates of 300 individuals of the control material who were not supposed to have died of cancer showed that four of them had in fact died of that disease. Examination of the supposed cancer diagnoses showed them to be correct in 92 per cent of the cases, while of 687 persons not stated to have died of cancer, 58 per cent were so listed on the death certificates.

There were 17 leukemic probands who had at least one other case of leukemia in their family which could be verified, while the families of the control material had only one case of leukemia. This is a significantly higher incidence of leukemia in the patient material and cannot be attributed to chance. The familial incidence of leukemia in this material is at least 8.1 per cent.

The author believes that the hereditary factors operating in leukemia are common to all the different varieties of the disease because the frequency of the varieties of leukemia observed in 39 families was the same as the incidence of the different varieties of leukemia among 310 nonselected patients.

A significant correlation was found to exist between siblings for age of onset of leukemia. Since it is unlikely that two siblings would show the same disease at the same age by chance, the concept of genetic relationship is strongly supported. The familial incidence which amounts to at least 8 per cent of all cases is more than can be explained by coincidence. The demonstrated relation [of 8 per cent familial incidence] must be supposed to be genetic.

The most likely method of inheritance is believed to be failing dominance but with it due to a single gene or to several (polymaria) is left an open question. On the basis of the present data consisting of thirteen families from this study plus 16 from the literature the author believes that extrachromosomal inheritance may be excluded. Simple dominance and recessive inheritance are also excluded while sex-linked and sex-limited inheritance have not been demonstrated.

The investigation of a possible relationship between pernicious anemia and leukemia showed that in the 209 leukemic proband pedigrees there were 17 verified cases of pernicious anemia i.e. 8 per cent of the families. In the control material pernicious anemia was found in only 6 of the 200 families i.e. 3 per cent. The relationship between leukemia and pernicious anemia may in Videbäck's opinion be due to a hereditary disposition which leukemia and pernicious anemia may have in common with cancer. No genetic relation between leukemia and other diseases of the blood-forming organs was found.

The last section of this paper is devoted to the consideration of the genetic relation between leukemia and cancer. In the data of this study there were 319 cases of cancer (78.9 per cent) among 4041 relatives of leukemic probands while there were 218 cases (5.99 per cent) among 3641 relatives of the control group. The incidence of cancer is about 32 per cent higher in the patient material than in the control group—a statistically significant difference. The conclusion of this section is that a relation does exist between leukemia and cancer evident both in the greater frequency of cancer in relatives of leukemic individuals and also the frequent coexistence of cancer and leukemia in the same patient. Leukemia is therefore believed to be a malignant neoplasm of the blood and the hemopoietic apparatus.

This study is an attempt to answer problems on a factual basis. Though conclusions are few the methods of the study and its objectives are worthy of high praise. Probably few other people recognize as clearly as does the author that much more data from unimpeachable sources is necessary before final conclusions can be reached. Investigators of leukemia and cancer will find occasion to return to this work for it will serve as a useful basis of comparison for their own data.

I. LUDWIN

*Submicroscopic Morphology of Protoplasm and its Derivatives*. By A. FREY WYSSLING. New York: Elsevier Publishing Co. Inc. 1948. Pp. 255, with 38 tables and 160 figs.

This monograph is the second edition of Frey Wyssling's *Submikroskopische Morphologie des Protoplasmas und seiner Derivate* first published in 1938. Extensively revised and rewritten, it has been excellently translated by Prof. J. J. Hermans and Miss M. Hollander.

The clear and exact style of this book makes it a pleasure to read and it should become familiar to all cytologists, cell physiologists, and biophysicists as the best existing presentation of the subject. It will act to the student who is unfamiliar with submicroscopic phenomena as a key to a new world. Even for the specialist, almost every page will be found to contain some piece of unfamiliar and interesting information, but the book is more than a mine of material; it is unusually evocative of ideas for future investigation, many of which will probably come to mind only after it has been read and laid down.

The first section, on the Fundamentals of Submicroscopic Morphology, deals with the organization of solids and the structure of gels; the second section deals with the fine structure of protoplasm (cytoplasm, nucleus, chloroplast, and the erythrocyte) and the last section deals with the fine-structure of the protoplasmic derivatives (cellulose, chitin, fibroin, keratin, collagen, myosin, and starch grains). There is a selected bibliography of over 700 references, together with a subject and an author index. Most of the figures have been introduced to illustrate the spatial arrangements of atoms, molecules, and larger structures discussed in the text; this they do so clearly that it would be possible to become acquainted with the outlines of the subject by studying the figures alone.

ERIC PONDOR

### Erratum

An unfortunate error in the preceding issue of *Blood* (June 1949), in the section on correspondence concerning revised hematologic nomenclature, gives a misleading impression. Page 781, the first sentence following the references to Dr. Osgood's letter should read: "A subsequent letter received from Dr. Jones indicates that Dr. Downey was unable to attend two of the last meetings of the Committee, and that he does not agree on all points with the report." (Instead of "Dr. Downey indicates that he was unable to attend.")

AUGUST, 1949

### FAMILIAL HYPOCHROMIC ANEMIA ASSOCIATED WITH POSTSPLENECTOMY ERYTHROCYTIC INCLUSION BODIES

By HAROLD MILLS, M D , AND S P LUCIA, M D

RECENTLY there has occurred a renewed interest in the subject of erythrocytic inclusion bodies, and emphasis has been placed on their appearance following splenectomy.<sup>1,2</sup> At the same time, there has been published an increasing number of reports bearing on the familial and congenital character of various hematologic disorders.<sup>4-7</sup> Therefore, it seems pertinent at this time to report a case of familial hypochromic, microcytic anemia in which large numbers of erythrocytic inclusion bodies were found in the peripheral blood following splenectomy.

#### CASE REPORT

##### *First Entry (7/15-7/17/36)*

B W a 27 year old white married male of German Irish and French descent was first seen at the University of California Hospital on July 15 1936. He had been anemic as long as he could remember but was able to continue normal activity as a grocer and postal clerk until the time of admission. For two months prior to entry he had been plagued by a dull aching left upper quadrant pain associated with moderate weakness and dyspnea. His physician found the hemoglobin to be 26 per cent ordered transfusions and then referred him to the University of California Hospital for diagnosis.

*Family History* His family history revealed that his mother died of Bright's disease and his maternal half brother (then 17 years of age\*) had also suffered from anemia. An examination of the patient's

From the Divisions of Medicine and Preventive Medicine University of California Medical School  
San Francisco Calif

\*Through the courtesy of Mr Harry Potter Registrar of the Veterans Administration Hospital at Wood Wisconsin we have learned that the maternal half brother of our subject suffered from hypochromic anemia refractory to treatment. He was splenectomized on June 6 1945 and expired on September 17 1947 of anemia, with widespread thrombophlebitis peripheral emboli and cardiac failure. Despite many transfusions the erythrocyte count and the hemoglobin content fluctuated around the average of 3 000 000 and 8.5 grams respectively pre and postsplenectomy. The white counts varied between 15 000 and 25 000 with a differential count which averaged 25 per cent PMN's and 64 per cent lymphocytes. There was a moderate degree of anisocytosis poikilocytosis and hypochromasia of the erythrocytes. The platelet count was 24 000 per cu mm. The erythrocyte fragility test revealed hemolysis from 0.46 to 0.32. The Wintrobe indices were as follows: Volume index 1.0 color index 0.85 MCHc 25 per cent MCV 104. A Price Jones curve of the erythrocytes (done by H.M.) revealed a mean corpuscular diameter of 7.62. Unfortunately no correlative blood counts were available. MCHc conc 0.25 saturation index 0.84. The sedimentation rate was 6 mm/hour. The reticulocyte count was 0.2 per cent. The urinary

infant son (age 17 months) revealed a mild anemia with moderate anisocytosis. The blood count was Hemoglobin 74 per cent R B C 3,640,000 W B C 11,800—PMN Fil 11 per cent, PMN Nonfil 35 per cent, eosinophiles 1 per cent lymphocytes 79 per cent monocytes 5 per cent and myelocytes 1 per cent.

*Past History and System Review.* The past history and system review were noncontributory except for measles, chickenpox, whooping cough and smallpox acquired in childhood.

*Physical Examination.* The physical examination was essentially noncontributory except for slight cardiomegaly associated with a loud systolic apical, hemic murmur, a questionably palpable liver and a firm sharp-edged spleen felt 3 fingerbreadths below the lateral costal margin.

*Laboratory Data.* Hemoglobin 45 per cent R B C 2,790,000 W B C 5,120 (with a normal differential count). The erythrocytes revealed anisocytosis, poikilocytosis and achromia and the platelets were said to be increased. Observations on the urine, gastric content and erythrocyte fragility (Hamburger method) were normal. The Rose Bengal test (biliary excretion) and phenylsulphathiazole test were within normal limits. Roentgen examination of the gastrointestinal tract and chest revealed no abnormalities.

A diagnosis of chronic hypochromic microcytic anemia associated with splenomegaly (2 first stage Banti's syndrome) was made and splenectomy was recommended.

#### *Second Entry (9/22/36-2/19/37)*

*Interval History.* The patient was splenectomized by his local physician and returned to work two weeks later. He was asymptomatic until two weeks before the second entry at which time he complained of exertional dyspnea and noticed swelling and pain in his left thigh. Within the next week, the pain and swelling involved the left leg and the right thigh. Five days prior to the second hospital admission he suffered an attack of acute pleuritic pain in the right anterior chest. The pain subsided gradually, and there was no hemoptysis.

*Physical Examination.* The findings on physical examination were essentially the same as previously noted except for the presence of a well healed splenectomy scar and the signs of thrombophlebitis in both thighs and calves.

*Laboratory Data.* The hemoglobin varied from 12 to 60 per cent, the R B C from 900,000 to 3,000,000 and the W B C from 12,000 to 40,000 with a terminal drop to 7,500. The morphology of the leukocytes was always within normal limits and their differential counts revealed a slight increase in the percentage of polymorphonuclear cells. The platelet counts showed variations of 900,000 to 1,900,000. A Price-Jones curve of the erythrocytes (fig. 1) gave the following results: Mean erythrocyte diameter  $6.65 \mu\text{m} \pm 1.5$  (50 per cent were below  $7.0 \mu\text{m}$  in size and 35.6 per cent were  $6.0 \mu\text{m}$  or smaller). The erythrocytes revealed anisocytosis, poikilocytosis and hypochromasia. Twenty-four to 67 per cent of the erythrocytes contained inclusion bodies (fig. 2) which gave a positive prussian blue reaction. (This was demonstrated by treating blood films with a mixture of equal parts of 2 per cent potassium ferrocyanide and 2 per cent hydrochloric acid for twenty minutes, then washing and counterstaining with safranin.) Frequent observations on the bleeding time and the erythrocyte fragility failed to reveal any abnormalities. On occasion the coagulation time (Lee and White) was slightly hastened. A clot retraction test showed the clot to be markedly retractile (1 hour and 35 minutes for complete retraction). The urine was negative for urobilinogen, urobilin and bile on numerous occasions.

*Course in Hospital.* Despite intensive supportive therapy, including numerous transfusions, large doses of ferrous sulfate and large doses of liver extract (refined and crude) the patient expired on February 19, 1937. During his final hospitalization the following complications were noted:

1. On November 1 and on November 9, 1936, the subject presented symptoms suggestive of pulmonary infarct.

urobilinogen was 0.1 mg. per 100 cc. The icteric index was 8 and the serum bilirubin 0.16 mg. Examination of his peripheral blood smear and bone marrow (fig. 3) revealed erythrocytic inclusions in large numbers of the erythrocytes and normoblasts. These inclusions gave a positive reaction for iron. The clinical diagnosis was Anemia, primary idiopathic. At death the autopsy revealed the following pertinent findings: (1) Anemia profound primary type. (2) Posterior myocardial infarct recent with mural thrombosis and secondary cerebral and peripheral arterial emboli. (3) Hemosiderosis of the liver, spleen, pancreas and abdominal lymph nodes. (4) Fibrous thrombophlebitis of the left femoral vein.

— On November 25 he experienced pain in the right tonsillar region. Examination revealed blanching of the superior  $\frac{2}{3}$  of the right tonsil and of both the anterior and posterior faucial pillars. One week later the left tonsillar region became similarly involved. Thrombosis of the arterial supply to the tonsillar

FIG. 1.—PRICE JONES CURVE (PATIENT B W) Vertical axis indicates number of RBC horizontal axis indicates diameter of RBC

region was suspected in both instances and this suspicion was substantiated when within two weeks the upper  $\frac{2}{3}$  of both tonsils became sharply demarcated and sloughed out without hemorrhage or ulceration

- 3 On December 26, thrombosis of the left ante-cubital vein was noted
- 4 On January 12 1937 he experienced a bout of paroxysmal auricular fibrillation which lasted three hours

FIG 3 —(A) Microscopic view Wright's stain ( $\times 650$ , enlarged approximately  $\times 2$ ) revealing siderocytes in the peripheral blood of our subject's maternal half brother (B) Microscopic view of bone marrow of our subject's maternal half brother. Note siderotic material within normoblast

- 5 On January 15 edema of the left calf was noted which subsequently involved the entire left lower extremity and the adjacent abdominal wall to the level of the costal margin. This was considered to be due to thrombosis of the left common iliac vein.

6 Before death the anemia became more marked and generalized anasarca appeared.

*Autopsy Findings* A summary of the important features of the autopsy, which was performed by Dr C. L. Conner, follows:

## Anatomic Diagnosis

A Hemolytic anemia with (1) Splenomegaly (study of surgical specimen), (2) hyperplastic bone marrow (3) lymph nodes showing minor erythropoiesis (4) hemochromatosis of liver, pancreas, lymph node and bone marrow (5) generalized edema (6) terminal heart failure

B Chronic proliferative endarteritis pulmonary and other arteries

C. Pulmonary and left iliac thrombosis

D Infarcts of lungs and spleen (pre-operative specimen)

Antemortem thromboses were found in the right auricle the distal end of the incised splenic vein and in the left iliac vein with an extension into the inferior vena cava. No thrombi were found in the mesenteric vessels but two pulmonary infarcts were present.

A special note draws particular attention to the following. All tissues of the body contain a great deal more liquid than normal. While no definite edema is noted externally in the thigh for instance when the tissues here are cut through and manipulated a great deal of liquid can be expressed from them. This is true of other apparently non-edematous tissue as well. The whole body appears to be water logged. The blood is quite liquid and watery and shows an obvious extreme anemia.

The microscopic examination of the hematopoietic system is as follows:

*Spleen* Sections of the spleen show a diffuse increase in pulp so that the splenic follicles are widely separated from one another although the latter are not diminished in size. The pulp is made up of erythrocytes of all shapes showing remarkable poikilocytosis and all degrees of degeneration and hemolysis. There are at the same time many normoblasts present and a scattering of myeloid cells. There is no increase in fibrous tissue within the spleen but the capsule is somewhat thickened. An infarct with beginning organization around the edges is present. (Note: The spleen weighed 790 grams and two small accessory spleens were present. The organ was dark red in color.)

*Lymph Node* Several lymph nodes show edema without much other change. Others contain a large amount of pigment in phagocytic cells within the sinusoids. There is some increase in immature cells among the lymphocyte follicles outside of germinal centers. Some of these having small black nuclei may be young erythroblasts.

*Bone Marrow* This is definitely hyperplastic with most of the young cells appearing to belong to the erythroblastic series. Other immature cells are present in small numbers and there is the usual number of megakaryocytes. There is also a great deal of pigment [chiefly hemosiderin] scattered throughout.

*In summary* The immediate cause of death is obviously the profound edema of the lungs and heart failure with edema of all tissues although the remarkable amount of liquid in the interstitial tissue cannot be due to heart failure alone. This is undoubtedly due to an anoxia associated with profound anemia and an increase in the hydrophilic nature of muscle and connective tissue proteins. The underlying physiological change has apparently been an increase in hemolysis of red blood cells even though these are not more fragile than normal. The result has been anemia with erythropoietic activity of the spleen and bone marrow and to a less extent lymph nodes. Another effect has been the deposition of blood pigment in liver, pancreas, lymph node and bone marrow leading to a type of hemochromatosis. The ultimate etiological factors in all this are not apparent. There is also no explanation for the intimal proliferation and thromboses of vessels noted.

Aided by Dr. Stuart Lindsay (Department of Pathology), the sections were reviewed using the prussian blue and Giemsa stains. Since large amounts of hemosiderin in the cells and interstitial tissue of the reticulo-endothelial system gave the positive prussian blue reaction, it was impossible to identify any granules which might represent phagocytosed erythrocytic inclusions. A moderate amount of non-staining brown pigment was also present. Using the classification of Rath and Finch,<sup>3</sup> an abnormal amount (Grade IV) of hemosiderin was found in the sternal bone marrow.

The clinical and autopsy findings recorded above may be interpreted as follows:

The results of the postmortem examination are consistent with the diagnosis of hemolytic anemia, but this diagnosis is not compatible with the clinical and laboratory data. The data fit best in the diagnostic category of *Hypochromic, microcytic anemia secondary to a congenital defect in the ability of the hemopoietic system to utilize iron*. To support this diagnosis the following points are worthy of emphasis: (1) The absence of clinical or laboratory evidence of hemolysis. (2) An anemia of long duration, refractory to the usual therapeutic agents. (3) The family history of a maternal half-brother who suffered from a similar type of lethal anemia. (4) The absence of reticulocytosis despite large doses of iron as well as the presence of a surfeit of iron in the tissues.

The widespread hemosiderosis may have been due in part to multiple transfusions. Rath and Finch<sup>8</sup> have demonstrated excessive amounts of hemosiderin in the bone marrows of patients who had received multiple transfusions. A more reasonable explanation of the hemosiderosis in this case is that its deposition in the tissues is an expression of the inability to utilize iron despite its presence in adequate amounts. Wintrobe et al.<sup>9</sup> were able to produce, in swine fed a diet deficient in pyridoxine, a microcytic anemia which was associated with hyperferremia, a normal icteric index and hemosiderosis of the spleen, liver, and bone marrow. They believed that the anemia was due to faulty utilization of iron. A similar mechanism may operate to produce anemia in the human subject.

## DISCUSSION

### *I Definition of Inclusion Bodies*

In the broad sense, erythrocytic inclusion bodies may be defined as intracorpuscular structures having certain morphologic and tinctorial characteristics. The definition may be limited further by the recognition of two categories, false and true inclusions. The former are predominantly artefacts produced in the laboratory. The true inclusion bodies are structures which may be either nuclear or cytoplasmic remnants, the products of normal metabolic processes, or the result of some aberration in the metabolism of the various constituents within the erythrocytes. Accordingly inclusion bodies may be classified as

#### **I False Inclusion Bodies of the Erythrocyte**

##### **A Those produced by faulty technique**

1. Unclean equipment
2. Unfiltered stain

##### **B Those produced by subjecting blood films to certain chemical or physical agents<sup>10, 11</sup>**

##### **C Cabot's rings (?)<sup>12</sup>**

##### **D Bacteria and parasites**

#### **II True Inclusion Bodies of the Erythrocyte**

##### **A. Nuclear or cytoplasmic remnants<sup>13</sup>**

1. Howell Jolly bodies
2. Diffuse basophilia
3. Reticulocytic material

##### **B Those containing iron (siderocytes)<sup>14</sup>**

1. An expression of faulty iron metabolism<sup>1, 2, 3</sup>

- a Due to toxins
  - i Acquired hemolytic anemia<sup>3 13</sup>
  - ii Stippling found in lead poisoning<sup>3 13</sup>
  - iii Associated with bacterial toxemias severe burns or industrial solvent poisoning<sup>13</sup>
- b Due probably to a congenital defect in iron metabolism
  - i Familial hypochromic microcytic anemia<sup>4</sup>
  - ii Familial hemolytic icterus<sup>3 16</sup>
  - iii Anemia associated with flexed tail and belly spot in mice<sup>14</sup>
- 2. An expression of normal iron catabolism
  - a Siderocytes found in aging blood<sup>17</sup>
- 3 Unclassified
  - a. Those found in association with Banti's syndrome and other hematologic disorders<sup>1 15</sup>
- C Those found in toxic or deficiency conditions
  - i Heinz bodies of toxic irreversible anemias<sup>18 19 20</sup>
  - 2. Inclusion bodies of atabrine poisoning<sup>21</sup>
  - 3 Inclusion bodies found in pyridoxine deficiency<sup>2</sup>—may be siderocytes<sup>2</sup>

### *False Inclusion Bodies*

False inclusion bodies are artefacts of the erythrocyte, animate or inanimate, which may at times assume certain definitive patterns. Rinehart<sup>10 11</sup> treated blood films with a mixture of reduced phosphomolybdic acid and either potassium dichromate or phosphotungstic acid and was able to produce various well defined patterns of hemoglobin precipitation. More recently, Schleicher<sup>12</sup> has demonstrated that the Cabot's ring bodies are probably artefacts produced in the laboratory. He concluded that they represented denatured protein configurations produced by subjecting the red blood corpuscle to hemolytic agents.

We have examined preparations of bone marrow and peripheral blood in numerous hematologic conditions and have encountered occasional single inclusion bodies. Their significance remains in doubt, because they may be confused with spurious inclusion bodies produced by amorphous precipitate (a common occurrence with unclean cover-slips) or the precipitate from unfiltered stain. Frequently, artefacts are encountered which are semirefractile and which assume a bluish-purple appearance upon change of focus. Therefore, it is stressed that predictable morphologic, chemical and tinctorial characteristics must be satisfied before an erythrocytic inclusion may be classified within the category of true inclusion bodies.

In some circumstances, microorganisms such as streptococci and staphylococci may become attached to the surface of the erythrocyte and give the appearance of an inclusion body. On the other hand, other microorganisms, as the Bartonella and the Plasmodia of malaria, specifically enter the erythrocyte to produce inclusion bodies. Finally, it is possible that the products of metabolic change induced by microorganisms or viruses may simulate inclusion bodies. All such instances may be classified as examples of false inclusion bodies.

### *True Inclusion Bodies*

Enumerated among the true inclusion bodies of the erythrocyte are the Howell-Jolly body (probably a nuclear remnant), the granules of diffuse basophilia, and the reticulocytic material (probably the basophilic remains of spongioplasm)<sup>12</sup>

The nature of basophilic stippling in lead poisoning is still uncertain, although studies by Case<sup>18</sup> and MacFadzean and Davis<sup>3</sup> indicate that the stippling is caused by iron-containing granules, thus making the stippled cell basically similar to the siderocyte.

True inclusion bodies not containing iron are observed in the anemias secondary to such toxic agents as atabrin, erythrol-tetranitrate and sulfonamides. Mushett and Siegal<sup>21</sup> produced anemia and erythrocytic inclusions in rats, mice and hamsters by feeding them large doses of atabrin. These inclusions stain blue with Wright's stain, and give a negative reaction for iron.<sup>3</sup> They were also noted within the lymphocytes—a phenomenon not observed in studies of iron-containing inclusions.

The Heinz-body characteristic of irreversible toxic anemia has been described in the German literature. More recently, Fertman and Doan<sup>18, 19</sup> have reported the case of an elderly man who had been taking erythrol tetranitrate and in whom there appeared a fatal refractory anemia characterized by erythrocytes containing Heinz bodies. Figge<sup>20</sup> was able to reproduce Heinz bodies in 90 per cent of the erythrocytes of mice by feeding them a 0.3 per cent solution of sulfanilamide in distilled water. He concluded that the tendency of various sulfonamides to induce Heinz bodies paralleled their ability to produce hemolytic anemia. The Heinz body is best seen in supravitral preparations, does not stain with Wright's stain and gives a negative prussian blue reaction.

Wintrobe et al.<sup>9</sup> fed pigs a diet deficient in pyridoxine following which the animals developed a microcytic anemia. The anemia was associated with a rise in serum iron concentration and hemosiderosis of the spleen, liver and bone marrow. There was no associated rise in the icteric index. As the anemia developed, the erythrocytes were found to harbor a moderately large blue-staining granule resembling a nuclear particle.

## II *The Problem of Iron Containing Inclusion Bodies*

The most important of the true inclusion bodies of the erythrocyte are those which give a positive prussian blue reaction indicative of the presence of iron. These cells were called siderocytes by Grüneberg,<sup>14</sup> who first described them in observations made on the anemia associated with the flexed-tail and belly-spot phenomenon of mice. He found that the erythrocytes of these animals at birth contained large numbers of inclusion bodies. As the animals matured, the anemia characteristic of the condition subsided, and there was a concomitant decrease in the number of siderocytes found in the peripheral circulation. Grüneberg also demonstrated that the fetuses of normal mice harbor siderocytes which disappear shortly after birth, and he also observed siderocytes in the heart blood of a human fetus (14 weeks old), as well as in the blood of four premature and full term human fetuses (33 to 40 weeks old).<sup>22</sup>

Pappenheimer, Thompson, Parker and Smith<sup>2</sup> reported 3 cases of anemia with splenomegaly, 2 of acquired hemolytic anemia and 1 an undetermined type of anemia. After splenectomy, examination of the peripheral blood of these subjects revealed large numbers of erythrocytes containing inclusion bodies. In an attempt to define the nature of these, Pappenheimer et al. showed that the bodies gave a

positive prussian blue reaction when stained in blood smears as well as in sedimented laked blood. The bodies were anisotropic, gave a negative Feulgen reaction (for nucleic acid) and the iron they contained was neither ferritin nor hemosiderin. The inclusions were gram-negative, did not stain with hematoxylin, did not contain alkaline phosphatase, nor did they fix complement. When a sample of heparinized blood was placed in a magnetic field, erythrocytes containing the inclusion bodies became concentrated along the line of magnetic contact. A significant number of granules morphologically similar to those observed within the erythrocytes were noted in the reticulo-endothelial cells (Kupffer cells, histiocytes and splenic endothelial cells) of two subjects and in the third, they were encountered in small numbers within the splenic endothelial cells.

MacFadzean and Davis,<sup>2</sup> stimulated by the work of Pappenheimer,<sup>2</sup> have published a comprehensive study and review of erythrocyte inclusion bodies, and emphasize their importance in acquired hemolytic anemia. They state that the inclusions are most commonly coccoid granules varying in size from 0.5 to 2.0 micra in diameter and usually located in the periphery of the corpuscle. Their form is frequently bacillary or tadpole-shaped and occasionally they assume amoeboid, diploid and tetrad forms. Should more than one body be found within the corpuscle (especially common following splenectomy), variation in size is the rule. The granules may form a solid mass of material and leave only a thin rim of hemoglobin in the periphery of the erythrocyte. Furthermore, they state that erythrocytes which contain large numbers of inclusion bodies tend to be smaller than normal. When viewed in unstained preparations, the inclusions appear as refractile colorless structures, when stained with the Leishman, Wright, or Giemsa preparations, they stain a purplish-blue although light blue and reddish-purple forms are sometimes observed as well as rodlike forms which stain alternately light and dark. The most important characteristic of the inclusion body they describe is its positive reaction for iron.

MacFadzean and Davis examined the bone marrow of patients whose peripheral blood contained erythrocytic inclusion bodies and noted their presence only in those cells of the erythroid series which were hemoglobinized. Cells showing minimal hemoglobinization were said to contain inclusions that were in close proximity to the nucleus, but as hemoglobinization increased, the granules gradually shifted toward the periphery, the position which they occupy in mature erythrocytes. Occasionally granules identical with those described within the red blood corpuscles were seen lying free in the marrow or within monocytes and reticulum cells, but not within any of the other varieties of leukocytes. They also noted granules within the endothelial cells of the spleen.

MacFadzean and Davis described 7 cases of acquired hemolytic anemia, 6 of which had been splenectomized. Before splenectomy, the maximum siderocyte count was 11 per cent or less, and following splenectomy it varied from 16 to 88 per cent. These authors postulate that corpuscles containing inclusions are defective cells rapidly eliminated from the circulation by the reticulo-endothelial system, especially that of the spleen. In support of this hypothesis they present some interesting data. Before splenectomy, they found inclusion bodies within a

large number of bone marrow normoblasts, and only small numbers of inclusion bodies within the erythrocytes of the peripheral blood. In 4 patients who were examined after splenectomy, the number of affected corpuscles in the peripheral blood was found to be increased and more closely approached the number of affected normoblasts in the bone marrow. They state, "it is evident that the rise in the total red cell count, for a variable period after splenectomy, can be accounted for entirely by the increase in the absolute number of inclusion-containing erythrocytes, since the number of unaffected cells showed little change."

Case<sup>17</sup> has investigated the occurrence of siderocytes in blood of cats, dogs, and human beings, stored outside the body. He found that siderocytes appeared with regularity as the stored blood aged, although certain agents modified the rapidity of their appearance. Depressed temperatures, carbon monoxide and glucose inhibited the rate of siderocyte formation, whereas heat and hemolytic agents such as phenylhydrazine accelerated the process. As siderocytes appeared, granules were seen to lie free in the plasma, and leukocytes, especially macrocytes, phagocytosed the siderotic material. A normal human volunteer was given phenylhydrazine following which the red blood cell count and hemoglobin content of the blood became decreased, and the blood and urinary siderocyte count rose. With recovery and the associated appearance of young cells, the siderocytes disappeared. Case concluded from these experiments that all erythrocytes go through a siderocyte stage during which they are susceptible to phagocytosis. Furthermore, he states that siderocytes are probably old cells and that the siderotic material is catabolic iron. He also is of the opinion that the siderotic granules he observed in the erythrocytes were probably different from the granules described by Pappenheimer.<sup>2</sup>

In an examination of 279 blood samples from normal persons, Case<sup>18</sup> found a maximum siderocyte count of 0.8 per cent while MacFadzean and Davis<sup>3</sup> failed to find any inclusions in 62 peripheral blood smears taken from normal individuals. Case also demonstrated siderocytes in hypochromic microcytic anemia, hemochromatosis, bacterial toxemias, severe burns, industrial solvent poisoning, lead poisoning, untreated pernicious anemia, sickle cell anemia and acholuric jaundice. The author states that all of these conditions, except hemochromatosis, are hemolytic processes and that the siderocyte levels follow the severity of hemolysis rather closely.

The papers of MacFadzean and Davis<sup>3</sup> and Pappenheimer et al.<sup>2</sup> stress the importance of splenectomy as the factor which precipitates the appearance of erythrocytes containing inclusion bodies, and the former emphasize the fact that the greatest number of these cells are found in subjects suffering from acquired hemolytic anemia who are splenectomized. Doniach, Grunberg and Pearson<sup>1</sup> have reported a case of Banti's syndrome in which the peripheral blood contained 30 per cent siderocytes following splenectomy. These investigators found 1 per cent or less siderocytes in the peripheral blood after splenectomy in a case of thrombocytopenic purpura, two cases of traumatic rupture of the spleen, and one case of possible splenic anaemia. Pappenheimer<sup>2</sup> demonstrated granules similar to erythrocyte inclusion bodies in the splenic sinus endothelium of a majority of cases of thrombo-

cytopenic purpura and rheumatic fever, and to a lesser extent in Banti's syndrome and hemolytic jaundice.

Otto and Rezek<sup>23</sup> report a case of lethal anemia associated with fever, splenomegaly, leukopenia and thrombocytopenia. A moderate number of erythrocytic inclusion bodies were observed preoperatively in the peripheral blood, and they became markedly increased in number following splenectomy. Although these inclusions fitted the description of siderotic granules, they believed them to be Bartonella bodies, despite the negative results of extensive cultural and inoculation studies. Horne, Lederer, Kirkpatrick, and Leys<sup>16</sup> report a family (diagnosis: congenital hemolytic disease) in which 6 members developed hemolytic crises within a few days. During the crises, many of the erythrocytes were observed to contain inclusions which they believed were Howell-Jolly bodies. The inclusion bodies they describe satisfy the morphologic characteristics for siderocytic inclusions. Unfortunately, the inclusions were not stained for iron by either Otto and Rezek or Horne et al.

Examination of the peripheral blood of our subject revealed that 24 to 67 per cent of the erythrocytes contained inclusion bodies (fig. 2). The inclusions stained purplish-blue with Wright's stain, and after decolorization and restaining gave a positive prussian blue reaction. Morphologically, they were similar to those described by the authors mentioned above. Although occasional cells were seen in which one granule only was visible, the majority contained multiple granules, and some cells contained five or more inclusions which formed a solid mass of material within the cell. Most of the inclusions were coccoid, although other forms were occasionally seen. Examination of the bone marrow and peripheral blood of a maternal half-brother (see footnote, pp. 891-2) revealed inclusion bodies in both the normoblasts and erythrocytes, the inclusions being similar in morphology to those observed in the erythrocytes of our subject (fig. 3). Unfortunately, specimens of bone marrow before splenectomy were not available for examination.

In summary, the inclusion bodies demonstrated in the erythrocytes of our subject (and his maternal half-brother) and those described in the papers of Grüneberg,<sup>1</sup> Case,<sup>18</sup> Pappenheimer et al.,<sup>2</sup> and MacFadzean and Davis,<sup>3</sup> all gave a positive iron reaction. This characteristic places them in the category of siderocytes. It seems likely that the siderocytes described by Case<sup>17</sup> and found in aging blood do not have the same fundamental significance as the inclusion bodies described by other workers. The relationship between the siderocytes which Grüneberg<sup>14</sup> found in fetal human blood and in the anemia of mice exhibiting the flexed-tail and belly-spot phenomenon and those found in human disease processes will have to await further clarification.

### III The Significance of Heredity in Anemia

In regard to the familial characteristic of the anemia observed in this instance, it would be advisable to emphasize the distinction between congenital and hereditary anemias. A congenital anemia may be defined as one existing at birth and acquired *in utero*. The anemias of this type may be due to metabolic disturbances, nutritional

defects, or iso-immunization phenomena. An hereditary anemia may be defined as one due to a constitutional defect, transmitted from parent to offspring. Familial hemolytic icterus, sickle cell anemia and Mediterranean anemia are examples of hereditary anemias. The mechanism of their transmission has been recently clarified.

Valentine and Neel<sup>6</sup> have demonstrated that Mediterranean anemia exists in two forms, one, thalassemia minor, a relatively benign disease characterized by mild anemia, ovalocytosis, target cells, the frequent occurrence of mild splenomegaly and a good prognosis, the other, thalassemia major, is characterized by more prominent features and a poor prognosis. These authors offer the hypothesis that thalassemia minor is due to heterozygosity for a factor which when homozygous results in thalassemia major.

The problem of ovalocytosis (elliptical erythrocytes) has been studied by Wyandt, Bancroft and Winship<sup>7</sup> and shown to be an hereditary trait more frequent in males than in females. Although they consider the anomaly to be a benign manifestation, a more recent review<sup>24</sup> emphasizes the fact that occasionally ovalocytosis may be associated with anemia.

Haden<sup>5</sup> has reported two families in which he found 8 patients afflicted with congenital hemolytic anemia without spherocytosis. The erythrocytes tended to be macrocytic and the fragility tests were within normal limits. A prominent feature in one family was the high percentage of stippled cells. Rundles and Falls<sup>4</sup> have reported two families in which the male members, through several generations, showed hypochromic, microcytic anemia associated with deformed erythrocytes. The females of these families appeared to transmit the disease. None of them suffered from anemia, although many had splenomegaly and minor red cell deformities such as ovalocytosis. A male subject of one of the families was splenectomized because of severe anemia, and following the removal of the spleen, inclusion bodies similar to those described by Pappenheimer were noted within the erythrocytes. They also report the case of a male unrelated to the two families, who was splenectomized, following which 40 per cent of the corpuscles were noted to contain inclusion bodies. The subject died one year later and the autopsy revealed diffuse hemochromatosis. Rundles and Falls consider this type of anemia to be a sex linked abnormality, the female carrying the recessive or incompletely recessive gene.

In view of these data, it is probable that the subject of this report falls within the category of hereditary anemia described by Rundles and Falls. The history of anemia since childhood and the similar hematologic and clinical course of his maternal half-brother are offered as evidence for the assumption. The mild anemia found in the infant son of our subject is somewhat out of line with the hypothesis since his mother was hematologically normal. However, this information should not materially affect the above conclusion.

#### *IV The Relation of Postoperative Thrombocytosis to Thrombosis*

A third most interesting feature of this case was the marked and persistent post operative thrombocytosis (as high as 1,900,000), associated with clinical and pathologic evidence of thrombophlebitis. Rosenthal<sup>25</sup> and Evans<sup>6</sup> were among the

first to show that splenectomy is frequently followed by postoperative thrombocytosis. Furthermore, Dawbarn, Earlam and Evans<sup>7</sup> have shown that any major operation, including childbirth and especially caesarean section, may be followed by a rise in the platelet count which reaches a maximum about the tenth post-operative day and subsequently declines toward normal. Adams<sup>8</sup> confirmed the work of Dawbarn et al. in regard to postoperative thrombocytophilia, and reported that 4 of 5 patients who exhibited postoperative platelet counts above 1,000,000 did not have clinical evidence of thrombosis. The relationship between thrombocytosis and siderocytosis is not within the domain of this paper, although they may bear a common relationship to the problem of thrombosis, a prominent feature of the case given in this report as well as that of his maternal half brother.

### SUMMARY

A case is presented of familial, hypochromic, microcytic anemia, associated with the appearance of siderocytes in the peripheral blood following splenectomy. The medical literature of the recent past focuses attention on the clinical recognition of inclusion bodies, but their origin and significance have not been completely clarified. Rundles and Falls<sup>4</sup> were the first to demonstrate them in hereditary hypochromic microcytic anemia, and in addition they have been shown to appear in acquired hemolytic anemia,<sup>2</sup> Banti's syndrome,<sup>1</sup> lead poisoning,<sup>3</sup> and in hemochromatosis, bacterial toxemias, industrial solvent poisoning, sickle cell anemia and acholuric jaundice.<sup>16</sup>

It is probable that the anemia in the case under discussion may have been due to some defect in iron metabolism. Neither the subject nor his maternal half-brother were demonstrated to have any objective evidence of hemolysis, and neither revealed reticulocytosis, despite intensive iron and liver therapy, a point in favor of poor utilization of iron. Furthermore, marked hemosiderosis was an outstanding feature of both cases signifying that at least one form of storage iron was available but not utilized.

The significance of inclusion bodies within erythrocytes is discussed and a classification of inclusion bodies is offered. A final statement regarding the nature of iron granules within red cells must await further research. When present within the erythrocytes of the peripheral blood or in the erythroid series of the bone marrow, they probably are the result of faulty iron metabolism either due to some inherent defect or secondary to the action of some noxious agent. Their prognostic significance is obscure, but this is probably related to the severity of the disease process of which they are an expression.

metal into compounds suited for intravenous injection the preparation of blood samples for radioactivity measurement and the use of differential counters for the simultaneous measurement of  $\text{Fe}^{55}$  (by x-rays) and of  $\text{Fe}^{59}$  (by beta ray) have been described by Peacock et al.<sup>8</sup> For most of the experiments  $\text{Fe}^{55}$  (half-life four years) was used. Various acidified salts were employed including ferric chloride, ferric-ammonium citrate, and ferrous ammonium sulfate. Carrier iron had been added to bring the total iron content injected to 0.1 and 0.5 mg. and each injection contained approximately one million counts per minute. As far as could be determined, these compounds were handled in identical fashion in the body when given intravenously. Over a period of two to three weeks after the injection of radioiron, samples of venous

blood were obtained in the morning the patient was fasting in most instances. Hematologic studies were done according to the following methods. Hematocrit determinations were performed in Wintrobe tubes with centrifugation for one hour at 3 000 r p m (International Centrifuge Size I Type C) hemoglobin was determined in duplicate by the oxyhemoglobin method on an Evelyn colorimeter<sup>9</sup> red counts were done in duplicate pipets and were repeated if they did not check within 5 per cent. Reticulocyte counts were done according to the method of Osgood and Wilhelm.<sup>10</sup> Cell constants were determined and reticulocyte counts were performed at least twice during the study of each patient. In all patients whose blood picture was stabilized during the period of study the figures were averaged in table 1 for the sake of brevity. In the others blood values at the initiation of the study are recorded.\* Bilirubin determinations were made according to the method of Evelyn and Malloy.<sup>11</sup> Blood volumes were determined by the method of Gibson and Evans.<sup>12</sup> Four to six samples of blood were drawn between ten to thirty minutes after injection of the dye and read in the Evelyn photo-electric microcolorimeter. The circulating red cell volume was taken as 85 per cent of the cell volume calculated from the plasma volume and venous hematocrit.<sup>13</sup> The radioactivity present in the blood stream which was solely intracellular after the first day was expressed as per cent utilization of the total quantity given according to the formula: Per cent utilization =  $\frac{(\text{counts per minute/cc red cells}) \times (\text{red cell volume})}{\text{Total counts/minute injected}}$ . Since a dilution of the iron injected was run with the samples obtained from the patient decay in radioactivity and variation in counting efficiency were automatically corrected.

## EXPERIMENTAL DATA

### I Normal subjects (Nos 8, 9, 10, 58, 87, 91, 93, 94)

Nine normal male volunteers between the ages of 24 and 30 were used as subjects. None had recently given blood, or suffered any other blood loss. Blood volumes were determined at the beginning and in five instances at the end of the experimental period. Hematologic data are recorded in table 1. Utilization of intravenously injected radioiron is recorded in figure 1. Over a period of fifteen to eighteen days, 8 of these subjects showed a utilization of between 68 and 83 per cent, averaging 74 per cent †.

Three subjects (71, 42, 43) with miscellaneous diseases not expected to alter iron metabolism were studied in a similar manner. These included a 59 year old female diabetic (71) recovering from mild diabetic acidosis, a 53 year old male with typical myocardial infarction (42) but without any fever or evidence of heart failure during the period of study, and a 71 year old asthmatic (93) in no acute distress. Their utilization curves shown in figure 2 were similar to the composite curve of normal subjects.

### II Iron Deficiency and Blood Loss Anemia (5, 7, 19, 20, 24, 26)

Six patients with acute or chronic blood loss were given radioiron ( $\text{Fe}^{55}$ ) intravenously. The patients represented varying degrees of iron deficiency as shown in table 1 by their degree of microcytosis and hypochromia. Slight increases in mean cell size found in acute blood loss are undoubtedly due to the appearance of younger cells which are larger. Some patients had continued bleeding, some were

In the reprints of this article charts are included portraying the clinical course of these patients similar to those shown in figure 7. While a correlation of the clinical factors affecting erythropoiesis and the utilization curve was thought to be important space did not permit its inclusion in the Journal.

† Subject 93 was excluded because of his variation from the others and because of the finding of a decreased amount of iron binding protein in his serum.

FIG 1

FIG 2

given iron therapy, some showed limited red cell production due to iron lack, while in others red cell regeneration was rapid. Patients 7, 19 and 26 showed a fall in the utilization curve during the second week. This may be related to changes in the total blood volume, since only an initial blood volume determination was made and subsequent changes in cell mass were calculated from the hematocrit.

FIG 3

It might also be explained by continued blood loss. All patients, however, showed a rapid utilization of the injected radio-iron (fig 3).

### III Hemochromatosis (83, 86, 108)

Three patients with hemochromatosis confirmed by liver biopsy were studied. While 2 patients had slight anemia and microcytosis, patient 86 had normal blood values (Table 1). The radioiron utilization curve of all patients was depressed (fig 4) in the presence of fairly normal red cell production.

### IV Refractory, Aplastic, and Myelophthisic Anemia (11, 14, 66)

Three different types of bone marrow dysfunction were studied. Patient 11 was a 22 year old woman with refractory anemia and a hyperplastic bone marrow. Patient 14, had acute disseminated lupus erythematosus with an aplastic marrow at post mortem examination and Patient 66, had extensive lymphosarcomatous involvement of the bone marrow. In these cases only small amounts of radioactivity appeared in the peripheral blood (Fig 5).

## HEMOCHROMATOSIS

FIG 4

## REFRACTORY APLASTIC AND MYELOPHTHISIC ANEMIAS

FIG 5

### V Uremia (4, 15, 29, 41, 62)

The five cases of renal disease included one patient with acute glomerulonephritis (29), 2 patients with lower nephron damage (41, 62) and 2 with chronic nephritis without edema (15, 4). In Patients 4, 15, and 41 blood transfusions had previously been given. All showed some degree of anemia (table 1), thought to be due to the uremic state, except for 41, where severe hemolysis had resulted in both renal damage and anemia. Utilization curves (fig. 6) were all depressed below normal.

FIG 6

### VI Infection (17, 18, 27, 44, 48, 57, 69)

Eight patients with infection of viral, bacterial, and protozoal etiology were studied. These infections were of variable duration. 44, 57, 27, and 17 were of less than two weeks duration. 69 and 46 of about one month, and the two patients with subacute bacterial endocarditis (18 and 47) of several months duration. In figure 7 are shown the clinical course of a patient with a mild viral pneumonitis and a patient with severe pneumococcal pneumonia. Iron utilization curves, shown in Figures 8 and 9 are extremely depressed in the severely ill patients.

### VII Hemolytic Anemia (2, 3, 52, 40, 75)

One patient with sickle cell anemia (2), one with congenital hemolytic anemia (3) and three with acquired hemolytic anemia were studied. Several of these

FIG 7

FIG 8

FIG 9

patients had been repeatedly transfused before the radioiron was injected (75), or were given blood during the period of study (40, 52). In only the patient with sickle cell anemia was there no blood administration. All cases showed a rapid initial rate of utilization and maximum values were obtained in three to five days (fig. 10). However, the total amount in circulation was very low. The utilization curve of Patient 3 was repeated one year after her hemolytic episode at a time when her peripheral blood picture was normal (fig. 11). In the interim she had lost no blood other than the normal amount through menstruation. The only difference between the two utilization curves might be assumed to be the state of severe hemolysis during the first study.

Fig 10

### VIII Pernicious Anemia (49, 53, 55)

Three patients with pernicious anemia were studied during a period of active blood production following liver therapy (fig. 12). In 53 and 55, the radioiron was given before liver therapy was effective, and the utilization retarded. In Case 49, however, iron administered several days after liver therapy was utilized rapidly and an early plateau was reached.

### IX Malaria (28, 51, 64, 80)

Radioiron utilization for hemoglobin synthesis was followed in 4 patients with paresis during a course of therapeutic malaria (*plasmodium vivax*). In figure 13,

## HEMOLYTIC ANEMIA

FIG 11

## PERNICIOUS ANEMIA

FIG 12

the dotted line represents periods of fever. It will be observed that the utilization of radioiron was markedly depressed during the malarial paroxysms and that in one instance the level of radioactivity fell (51). A fall in hematocrit also occurred in these patients during the active infection.

#### X Malignancy (45, 56)

Patient 45 was a 65 year old woman with probable adenocarcinoma of the left kidney and metastases to the right femur. Patient 56 was a 42 year old man

FIG 13

with a bronchogenic carcinoma, confirmed at autopsy. Both patients were afebrile and had no blood loss. Utilization curves were depressed (fig 14).

#### XI Endocrine disease (23, 25, 33, 35, 54)

Four patients with typical Addison's disease with a mild normocytic anemia were studied and utilization curves (fig 15) were found to be within normal range. A patient with postoperative myxedema (22) with a basal metabolism of  $-31$  also approximated normal utilization. However, patient 54, a 58 year old woman with anterior pituitary hypofunction showed a definite decrease in radioiron utilization (fig 16).

#### XII Miscellaneous (6, 12, 34, 31, 63)

A 23 year old girl with mild acute infectious hepatitis (6) showed normal utilization. A patient with Laennec's cirrhosis and obstructive jaundice (12) and

## MALIGNANT NEOPLASM

FIG 14

## ADDISON'S DISEASE

FIG 15

Patient 34, a 51 year old woman with toxic cirrhosis both showed utilization of 40-45 per cent at the end of eighteen days

A patient with polycythemia vera (31) who had been treated for two years by phlebotomies showed a rapid utilization to 90 per cent within the first week, while a patient with chronic congestive failure and secondary polycythemia (63), showed a normal utilization of iron for hemoglobin production

#### THYROID HYPOFUNCTION

FIG 16

#### DISCUSSION

The preceding data represents the utilization of injected radioiron for hemoglobin production in man. Problems which are raised in this type of study include (1) the irradiation hazard of the isotope injected, particularly since it is not excreted from the body, (2) the exchange rate between hemoglobin iron and other body iron, (3) the nature of the utilization curve including the pathway taken by injected iron and factors influencing its synthesis into hemoglobin, (4) the interpretation of the utilization curve in the various pathological states investigated.

#### *Irradiation Hazard*

An approximation of the radiation produced by the injected iron can be made. The normal adult has a bone marrow space ranging from 1,600 to 3,700 cc averaging 2,600 cc.<sup>14</sup> It is likely that only about one-half of this marrow is active in the sense that it is engaged in the formation of erythrocytes and leukocytes. Only

about one-fifth of the active marrow space is concerned with erythropoiesis, the other four-fifths producing white cells in the myeloid series

Using these values, however approximate, one may estimate the radioiron of the bone marrow or any fraction thereof, in an individual receiving one million counts per minute, of radioactive iron. Our normal build-up curves show about 75 per cent localization of the injected activity within the red cell mass. Therefore, 25 per cent or  $2.5 \times 10^6$  will be found in the fixed tissues. This amount will be contained in liver, spleen, and bone marrow for the most part. Let us assume that all of this activity is distributed evenly within the bone marrow. In the case of  $\text{Fe}^{55}$ , the counter efficiency is 0.03, according to Peacock et al.<sup>3</sup> Therefore,

$$(1) \quad \frac{2.5 \times 10^6}{0.03} = 8.3 \times 10^7 \text{ disintegrations per minute in the whole bone marrow}$$

Divided by weight of marrow in grams

$$(2) \quad \frac{8.3 \times 10^7}{2.6 \times 10^3} = 3.2 \times 10^4 \text{ or}$$

$$(3) \quad 3.2 \times 10^4 \times 5.9 \times 10^5 = 1.88 \times 10^7 \text{ ev/Gm./min. or}$$

$$(4) \quad 1.88 \times 10^7 \times 1.44 \times 10^2 = 2.71 \times 10^{10} \text{ ev/Gm./day or}$$

$$(5) \quad \frac{2.71 \times 10^{10}}{52 \times 10^{12}} = 0.0005 \text{ roentgens equivalent physical per day for } \text{Fe}^{55}$$

if all the activity in active marrow = 0.001 r.p./day and if all activity in erythropoietic areas = 0.005 rep/day

Similarly the counter efficiency for  $\text{Fe}^{59}$  is 0.25. Therefore

$$(1) \quad \frac{2.5 \times 10^6}{0.25} = 1.0 \times 10^6 \text{ dis./min. in whole marrow}$$

Dividing by weight of marrow in grams

$$(2) \quad \frac{1.0 \times 10^6}{2.6 \times 10^3} = 3.85 \times 10^2 \text{ dis./Gm./min. or}$$

$$(3) \quad 3.85 \times 10^2 \times 0.12 \times 10^6 \text{ ev} = 4.62 \times 10^7 \text{ ev/Gm./min. or}$$

$$(4) \quad 4.62 \times 10^7 \times 1.44 \times 10^2 = 6.64 \times 10^{10} \text{ ev/Gm./day or}$$

$$(5) \quad \frac{6.64 \times 10^{10}}{52 \times 10^{12}} = 0.0013 \text{ roentgens equivalent physical per day for } \text{Fe}^{59} \text{ if all activity in erythropoietic areas} = 0.013 \text{ rep/day}$$

The above data indicate the upper level of activity in bone marrow due to extra circulating radioiron. Since it is known that much of the activity is stored in the liver and spleen, and if an even distribution is assumed in all three organs, the calculated bone marrow radiation dose given above for red cell forming marrow should be multiplied by 0.13.

It, therefore, seems probable that the radiation due to extracirculating radioiron in those fixed tissues containing the highest activity will not exceed 0.0008 r/day for  $\text{Fe}^{55}$ , and 0.002 rep/day for  $\text{Fe}^{59}$  in the normal adult male injected with one million counts per minute. The tissue irradiation is, therefore, calculated to be from 1/50th ( $\text{Fe}^{59}$ ) to 1/100th ( $\text{Fe}^{55}$ ) of the maximum permissible dose of 0.1 r (or rep) per day.

The amounts of iron injected in these experiments represent about one ten thousandth of the total body iron and after injection raised the serum iron less than

10γ/100 cc Thus the radioiron may be regarded as a true tracer dose of iron which would enter into the normal body iron turnover without altering it in any way

### *Exchange of Hemoglobin and Tissue Iron*

Iron gains access to the red cell only in its developmental stage, to be synthesized into hemoglobin Studies with reticulocytes have shown an active uptake of radioiron by these cells in vitro<sup>15</sup> When mature erythrocytes are incubated with radioiron, no uptake occurs When radioiron is injected into patients with little or no bone marrow function, little or no radioactivity appears in the red cell mass Once incorporated in the cell, the iron remains fixed there until the cell is destroyed In patients with large iron reserves it is possible to determine the life span of transfused tagged cells, since the iron liberated from senescent erythrocytes is diluted by the large reserve stores and only a small portion is reutilized Free exchange of iron does not occur, therefore, between erythrocytes and plasma or tissues

### *Nature of the Utilization Curve*

The amount of radioactivity entering the circulation over a period of fifteen to twenty days is a composite of three interdependent parts of iron metabolism the serum iron transport mechanism, the size and availability of iron stores, and bone marrow function

Within ten minutes after injection, one-third to one-fourth of the radioactivity has disappeared from circulation and the remainder clears exponentially from the serum, 50 per cent in about one and one-half hours<sup>16</sup> This latter fraction is bound in the plasma to a B<sub>1</sub> globulin which functions as a transport protein for iron<sup>17</sup> The amount of injected radioiron initially bound to this protein is fairly constant, unless the protein is already saturated with iron

Much of the radioiron may be found in the liver within a few hours after injection<sup>18</sup> Granick and Hahn have found this to be in the form of ferritin iron which probably represents the more labile form of storage iron The radioiron is then rapidly rerouted to the bone marrow for hemoglobin production About half of the total utilization of radioiron for hemoglobin production occurs over a period of 2.2 days Assuming that this radioiron was first mixed with tissue stores and then carried to the bone marrow, we may calculate the reserve iron to be about 100 mg Storage iron in man is considerably greater than this, therefore, radioiron can not completely mix with iron in storage This has led to the postulation of a very small labile iron reserve\* It seems more in harmony with our observations to think of this not as a special form of storage iron, but to postulate that the iron has fallen on the topsoil of iron stores which would be more labile from a physical standpoint as suggested by Dubach, Moore, and Minnick<sup>7</sup>

\* Red cell life span has been established in man at about 120 days Therefore 0.83 per cent of blood is broken down and rebuilt each day In a blood volume of 5 000 cc containing about 2,500 mg of iron this amounts to 21 mg of iron If radioiron labels a small active compartment 50 per cent of which turns over every 2.2 days the compartment size to the first approximation would be 92 mg

Over the days following injection, the radioiron passes through the serum to the bone marrow. The functional integrity of the erythropoietic tissue is the final link in the incorporation of the radioiron into the red cell.

The curve of radioiron utilization for hemoglobin production in normal subjects is approximately exponential in character. When normalized to 100 per cent, this curve extrapolates to a theoretic lag period of 1.8 days. Actually there is an appreciable uptake during this two day period, considerably greater in certain pathologic states. This is at least partially explained by the observation that reticulocytes in vitro will take up radioiron. It might be presumed that the reticulocytes in the circulation and the cells just leaving the marrow would begin to assimilate radioiron immediately after its injection. In addition, the composite normal curve is derived from the numerical average of eight subjects and shows a straggling effect which in part explains this initial rise in the utilization curve.

#### *Interpretation of the Utilization Curve*

In interpretation of the utilization curve there are two components of importance: the size of iron stores, and bone marrow function. The influence of enlarged iron stores was demonstrated experimentally in dogs (table 3). Utilization curves done after iron injections showed marked depression although erythropoiesis was unaffected. A similar reduction in utilization has been produced in experimental subjects by oral ingestion of iron over a period of six months. This again occurred without change in peripheral blood or in serum iron levels. The effect of bone marrow dysfunction is self evident from previous discussion.

The normal curve shows the localization of about 25 per cent of the radioiron extravascularly and 75 per cent in circulation as hemoglobin. This pattern may be taken as representative of the average storage iron compartment size and normal bone marrow function. The extravascular iron admittedly represents iron incorporated in cell enzymes and myoglobin as well as storage iron. With a decrease in storage iron as in iron deficiency, there may be increased demands of tissue for iron. This would make it unlikely that decreased iron stores would be accurately detected by the per cent utilization of radioiron. In conditions of iron excess, however, it seems definite that increased stores have a clear-cut effect in depressing utilization of radioiron for hemoglobin production.

In *iron deficiency and blood loss anemia*, initial utilization is more rapid and complete than in normal subjects. Comparing the curve in figure 3, it will be seen that Patients 20 and 26 show a greater utilization than the others. This is explainable on the basis of a greater bone marrow activity in these cases, one showing a reticulocytosis of 17 per cent, and the other responding with a rise in hematocrit to iron therapy. It is of some interest that blood production in patients 25, 5, and 7 was not increased during the first week, as judged by the hematocrit. With the hyperplastic marrow found in iron deficiency and therefore an increase in total red cell elements, the cell turnover would be slower than normal. The iron given, 0 to 0.5 mg, as compared with a daily breakdown and reutilization of about 20 mg, would not be expected to accelerate cell production. We must conclude that the increased speed of utilization in these cases represents a decrease in

storage, and in serum turnover time and perhaps a slightly shorter period of hemoglobinization of the red cell in the marrow. As the rate of erythropoiesis is increased by supplying more building materials, the utilization is further accelerated. It is of interest that 100 per cent utilization is not attained, suggesting that certain tissue requirements are met even with anemia. In *hemochromatosis*, radioiron utilization is profoundly depressed, while there is nothing fundamentally wrong with erythrocyte production. This clearly indicates, as did animal experiments (table 2), that radioiron to some extent measures tissue iron stores in that its utilization is inversely proportional to their size.

TABLE 2.—*Iron Loading Experiment in Dogs*

	Initial utilization (Fe <sup>55</sup> )	Iron injected	Subsequent utilization (Fe <sup>55</sup> )
	per cent	mg	per cent
G	77	1500	24
S	75	4170	16

Fifteen kilogram mongrel dogs were given radioactive iron (Fe<sup>55</sup>) intravenously and its utilization followed for 15 days. Blood volume of Dog G was 1550 cc. with hematocrit of 48% blood volume of Dog S was 1350 cc. with hematocrit of 51%. Over the following three months iron was injected as iron ascorbate gelatin. Subsequent utilization curves were performed showing greatly depressed utilization. Autopsies of the animals showed large iron deposits throughout the reticuloendothelial system of both animals.

TABLE 3.—*Rate of Radioiron Utilization for Hemoglobin Production*

Condition	Average time to achieve 50% of the maximum utilization observed
	days
Hemolytic anemia	2
Iron deficiency anemia	3
Normal	4
Hemochromatosis	4
Infection	5 or more
Myelophthasic anemia	8 or more

In conditions associated with *bone marrow dysfunction* (refractory, aplastic and myelophthasic anemias), the amount of radioactive iron appearing in the circulation was considerably reduced and the utilization curve was flattened. This same pattern was present in *uremia* and the impairment in utilization was roughly proportional to the degree of azotemia. In some instances body iron stores had been altered by previous transfusions (patients 15, 4, 41). This was not enough to explain the depression observed, and as demonstrated in Patients 41 and 62, when nitrogen retention was alleviated, iron utilization was improved. This would suggest that some factor associated with retention of metabolic products interferes with blood production as measured by iron utilization. There would not appear to be an attendant disorder in iron metabolism here, as the serum iron is usually within normal limits in contrast to the marked depression observed in infection.

Among the eight patients with *infection* studied, there was no reason to believe that any difference in iron utilization existed attributable to the etiologic agent. Rather, the depression in utilization curves appeared to be proportionate to the general severity of the infection. The curves showed the same gradual daily increments characteristic of decreased red cell production with the exception of 2 patients (18 and 47). Both of these had subacute bacterial endocarditis with associated splenomegaly. The rapid initial rise and early plateau in their utilization curves are similar to the curves in hemolytic anemia and raise the question as to whether increased hemolysis may have been present. This depressed utilization of radioiron in infection associated with a profound lowering in serum iron has been described in experimental animals.<sup>18</sup> The patients with *hemolytic anemia* show a different type of curve. Maximum utilization is reached on an average by the fourth day in contrast to the more gradual plateau normally found. A second feature of interest is the extremely low utilization observed in most instances. Previous blood transfusions may have depressed the utilization to some extent. In only Patient 2 was the experimental period entirely free of blood administration. However, while larger iron stores are to be expected in hemolytic anemia, these do not begin to reach the size found in hemochromatosis. This would suggest that, in hemolytic anemia, the serum iron binding protein is almost completely saturated with iron from broken down erythrocytes with the result that the injected radioiron is at once deposited in inactive tissue stores. Figure 11 substantiates this, for the utilization curve during the acute hemolytic stage was only 15 per cent, while at a later date the utilization was 50 per cent. There was no reason to believe that iron stores had changed appreciably in the interim. This may indicate either that hemoglobin iron is necessarily used in preference to injected iron or that the transport mechanism was already saturated with iron and that the injected iron was therefore more rapidly taken out of circulation. Destruction of newly formed erythrocytes undoubtedly occurred in these patients. This would hasten the mixing of iron but would not necessarily effect the per cent utilization for hemoglobin production. *Pernicious anemia* presents a more complex situation. It will be observed that there are two types of curves. When the iron had opportunity to mix with the enlarged iron stores before liver therapy, its subsequent appearance in the circulation was slow. However, when the iron was given at a time when hematopoiesis was proceeding rapidly after liver therapy, utilization was rapid. This latter patient showed an early plateau, suggesting that by the fifth day there may be some destruction of the newly formed cells. Other observations on the viability of the reticulocytes in pernicious anemia<sup>16</sup> and studies<sup>20</sup> on the viability of erythrocytes in pernicious anemia substantiate this. In *malaria*, the decline in radioactivity in Case 51 indicates destruction of young cells in keeping with the previous observation that parasitized cells contain most of the radioactivity.<sup>21</sup> It will be observed that during the periods of fever there is little iron utilization, while after irradiation of the infection there is more rapid utilization.

Little is known of the mechanism of anemia in *malignancy*. The general contour of the utilization curve was fairly normal, but the utilization was less than half of normal. There was no evidence of hemolysis in these cases. It is impossible to

divorce the influence of storage size and bone marrow dysfunction here. It is reasonable to assume, however, that both may play a part. In keeping with the lack of any severe hematologic involvement in *Addison's disease*, the utilization curve was essentially normal. This was also true of mild myxedema. However, with the more severe anemia of panhypopituitarism, the utilization was depressed.

In figure 17, a diagrammatic representation of storage and circulating red cell iron in certain conditions was studied as compared with typical radioiron utilization

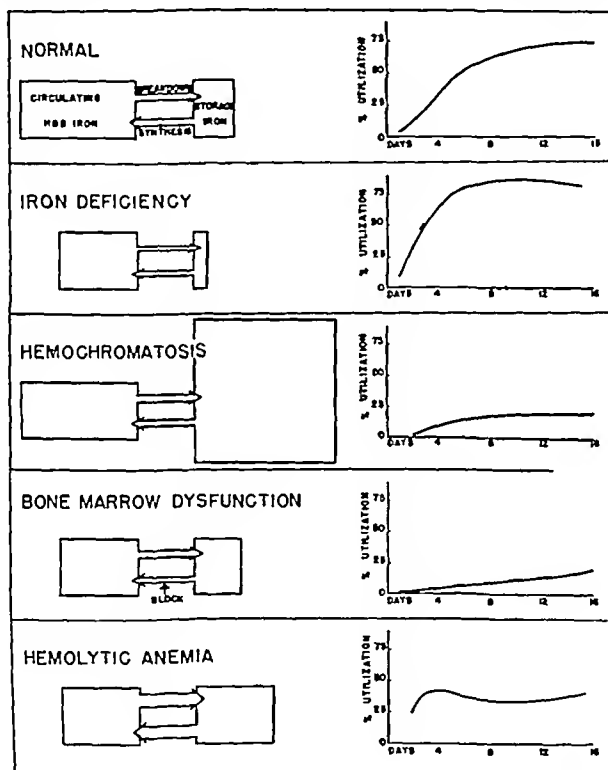

FIG 17

tion curves. In hemochromatosis and in iron deficiency, the primary factor influencing utilization was the size of iron stores. In hemolytic anemia and bone marrow dysfunction, the chief factor was rate of blood production in the bone marrow. It is of some interest that if the curves in both control subjects and in those patients with hemochromatosis are "normalized" to 100 per cent, their slopes are the same. In general, the slope appears to correlate with the rate of red cell production. As an index of this, the average time to reach 50 per cent of the utilization attained in two weeks is listed in table 3. The difference is somewhat

greater than apparent from the data when the period of lag is taken into consideration

These data are similar in general to the studies of iron utilization reported by Dubach, Moore, and Minnick.<sup>7</sup> Our lower utilization values may be accounted for in part by the assumption of blood volumes on the part of these authors without the additional correction factor of 0.85 per cent found necessary by Gibson et al.<sup>22</sup> Ross<sup>22</sup> finds a slightly lower normal utilization, in the neighborhood of 60 per cent. It seems likely that injected iron is used interchangeably with iron liberated from hemoglobin, for the utilization curves are quite similar from broken down hemoglobin and injected radioiron.<sup>2, 23</sup> The blocking action found in hemolytic anemias would appear to be due to the more saturated state of the serum iron binding protein forcing the injected iron into storage depots. In absorption studies employing radioiron, it is obvious, as previously suggested,<sup>7</sup> that the percentage utilization cannot be taken as the amount absorbed and that the studies of Hahn et al.<sup>24</sup> must be interpreted according to the expected utilization of iron, once this material gains access to the blood stream. The simultaneous intravenous injection and oral administration of different isotopes of radioiron might be expected to circumvent this.

#### SUMMARY

By determining the percentage utilization of intravenously administered radioiron for hemoglobin production over a period of two to three weeks, certain measurements of internal iron metabolism can be made.

With a normal rate of blood production, changes in per cent utilization reflect alteration in iron stores. Iron depletion is characterized by more rapid and more complete utilization of radioiron. States of iron excess in hemochromatosis can be identified by their profound depression of radioiron utilization.

If, on the other hand, storage iron is not greatly altered, the percentage utilization is determined by the function of the erythropoietic tissue. In myelophthisic anemias, in uremia, and in infection, a similar depression of the curve is found.

The rate of erythropoiesis may further be estimated by the slope of the utilization curve, and evidence of abnormal red cell destruction is found in early and abrupt plateau of the utilization curve.

A correlation has been made in a variety of hematologic disorders between the radioiron utilization for hemoglobin production and the clinical factors which might be expected to affect iron metabolism in these patients.

# HEMOLYSINS IN ACQUIRED HEMOLYTIC ANEMIA

## EFFECT OF pH ON THE ACTIVITY IN VITRO OF A SERUM HEMOLYSIN

By J. V. DACIE, M.B., M.R.C.P. LONDON

**H**YDROGEN ion concentration has a controlling effect upon many hemolytic systems, both simple and complex. Osborn<sup>1</sup> in 1934 reviewed the early literature on the effect of pH on the hemolysis by complement of corpuscles sensitized by hemolytic immune body. He found that the optimum reaction for the hemolysis of sheep corpuscles by guinea pig serum was about pH 7.5 with inhibition below pH 5.5 and above pH 9.7. More recently, Seifter et al.<sup>2</sup> have reported unimpaired activity of human complement between pH 6.1 and 8.4 and irreversible and rapid destruction below pH 4.2 and above pH 10.1.

The effect of pH or carbon dioxide concentration on the activity in vitro of hemolytic antibodies of human origin has seldom been considered except in the case of chronic hemolytic anemia with nocturnal hemoglobinuria (Ham,<sup>3</sup> Dacie and Richardson<sup>4</sup>), in cold hemoglobinuria where the adjuvant effect of carbon dioxide on hemolysis has been sometimes referred to (Van den Bergh,<sup>5</sup> Hannema and Rytma,<sup>6</sup> Wagley, Zinkham and Siebens<sup>7</sup>) and in a case of acute hemolytic anemia in infancy reported by David and Minot.<sup>8</sup>

In the present communication are reported observations on the activity in vitro of an abnormal hemolysin in the serum of a patient with idiopathic acquired hemolytic anemia, and the effect of pH on its action. It was found that although little or no hemolysis resulted when normal Group O corpuscles were suspended in unacidified patient's serum (pH 8.0), hemolysis readily took place if the pH of the serum-corpuscle suspension was adjusted to an optimum (pH 6.8 to 7.0) by the addition of suitable volumes of acid. If graded amounts of acid were added to serum it could be shown that the range of pH within which hemolysis could be observed corresponded quite closely to that found in chronic hemolytic anemia with nocturnal hemoglobinuria (Dacie and Richardson<sup>4</sup>). In the final section of this paper, these observations are contrasted with the pH ranges for the hemolysis by complement of erythrocytes sensitized by anti-A or anti-B isohemolysin and of group O erythrocytes sensitized by a cold hemolysin present in the serum of a patient with cold hemoglobinuria.

### GENERAL TECHNICAL METHODS\*

Serum was obtained by defibrinating blood around a roughened glass rod in a conical flask. The pH of the serum was approximately 8.0. Serum intended as a source of complement was used within three hours of collection and stored frozen until utilized.

The pH of the serum was modified by the addition of 10 per cent by volume of N/5, N/10 or N/20 NaOH or N/20, N/10, N/5, N/4, N/3, 5 N/3 or N/2.5 HCl.

From the Department of Pathology, Postgraduate Medical School of London, London, England.

\* Other technical details are given in footnotes to table 1.

*Erythrocyte suspensions* were prepared from packed saline washed corpuscles and used at final concentrations of 2 per cent or 5 per cent by adding to the (acidified) serum 10 per cent by volume of a 20 per cent or 50 per cent suspension

*Serum-corpuscle suspensions* were generally incubated in a water bath at 37 C for 30 minutes

*Hemolysis* was measured photoelectrically after diluting in N/200 NaOH volumes of the supernatants obtained after centrifuging the corpuscle serum suspensions

The pH of the corpuscle serum suspensions was measured by a glass electrode at the end of the period of incubation and after resuspending the corpuscles or when only small volumes of serum were available by the use of indicators (phenol red bromthymol blue or methyl red)

## SUMMARY OF CLINICAL HISTORY AND ROUTINE LABORATORY FINDINGS

*Miss B, aged 18 Idiopathic acquired hemolytic anemia*

Splenectomy had been performed for hemolytic anemia approximately five years before the present series of observations was made The cause of the original hemolytic attack was uncertain, the family history did not suggest a familial incidence

The patient was admitted into a hospital in London in December 1946, severely ill with signs of intense hemolysis Repeated blood examinations then revealed a severe macrocytic anemia, the erythrocyte count was 10 to 15 million per cu mm, with 35 to 55 Gm hemoglobin, there was a high reticulocytosis (25 to 50 per cent) and a raised mean corpuscular volume (up to 160 cu micra) In films of peripheral blood there were occasional normoblasts, much polychromasia and postsplenectomy basophilic stippling, and rarely instances of erythrophagocytosis by mononuclear cells The Coombs test was positive and cold autohemagglutinins were present to a titer of 1:512 at 2 C, there was just perceptible autohemagglutination at 37 C The plasma bilirubin level was continuously raised (up to 4 mg per 100 ml) and there was a slight increase in plasma globulin (albumin 40 Gm, globulin 33 Gm per 100 ml)

Hemolysis continued at an extremely rapid rate with only minor fluctuations, and blood transfusions were only of transient benefit Hemoglobinuria was generally absent, but was observed on several occasions after transfusions Data obtained by the differential agglutination technic (Dr J F Loutit) confirmed that the transfused blood was very rapidly eliminated The patient died in April 1947

## NATURE OF THE SERUM HEMOLYSIN

Samples of the patient's blood were investigated on several occasions between January and March 1947\* It was repeatedly found that normal group O erythrocytes and the patient's own corpuscles underwent hemolysis in vitro in the patient's serum The hemolytic antibody seemed to be distinct from the cold hemagglutinin antibody and was absorbed on to corpuscles better at 37 C than at lower temperatures The amount of hemolysis was largely determined by the pH of the cor-

\* I am indebted to Dr J F Loutit for blood from this patient and to Dr J F Hawkesley for details of the clinical history

1 a b c and d PROCEDURE The corpuscle serum suspensions were centrifuged after 30 minutes at 37 C. REMARKS Demonstrates the effect of pH on the hemolysis of the patient's corpuscles and of normal group O erythrocytes. The patient's own corpuscles are less sensitive than are the normal erythrocytes.

2. PROCEDURE (a) The corpuscles were sensitized in the patient's serum for 30 minutes at 37 C. The suspension was then centrifuged; the deposited corpuscles were washed in warm saline and resuspended in fresh normal acidified† serum and incubated at 37 C for a further 30 minutes. (b) Same as (a) but the corpuscles were sensitized in the patient's serum at 16 C. (c) Same as (a) but the corpuscles were sensitized in the patient's serum at 2 C. REMARKS Demonstrates that the hemolysin is less readily absorbed at temperatures below 37 C.

3. PROCEDURE The corpuscle serum suspension was incubated for 30 minutes at 37 C, then centrifuged and the corpuscles washed once in warm saline. The sensitized corpuscles were then divided into two equal portions (a) and (b). To (a) was added a volume of heated normal serum at its natural pH (8.0) to (b) was added heated acidified normal serum (pH 7.0). Both tubes were held at 37 C for 30 minutes, then centrifuged and fresh acidified normal serum added to the deposited corpuscles (pH 7.0 approx) and the suspensions incubated at 37 C for a further 30 minutes. REMARKS Shows that the hemolysin is absorbed best at a relatively acid reaction and may be liberated from the corpuscles into serum of a more alkaline reaction (a).

4. PROCEDURE (a) The corpuscle serum suspension was incubated at 37 C for 30 minutes, then centrifuged. To the deposit was added absorbed guinea pig serum. The tube was incubated at 37 C for one hour. (b) Unsensitized normal corpuscles were suspended in absorbed guinea pig serum and incubated at 37 C for one hour (control for a). (c) Incubated at 37 C for one hour. (d) Same as (c) but with the addition of absorbed guinea pig serum. REMARKS (a and b) Sensitized normal corpuscles are hemolyzed by fresh guinea pig serum complement. (c and d) Hemolysis is increased in the presence of additional guinea pig serum complement.

5. PROCEDURE (a) (1) The suspension was incubated at 37 C for 30 minutes, then centrifuged. Acidified fresh normal serum was added to the deposit and the tube incubated at 37 C for one hour.

puscle-serum suspension, hemolysis was maximal at about pH 6.8 to 7.0 and was inhibited below pH 6 and above pH 8, and there was but a trace of hemolysis in unacidified serum. This restricted pH-hemolysis range seemed due to the hemolysin being poorly absorbed at the alkaline side of neutrality, and it was demonstrated that hemolysin absorbed at the optimum pH was liberated again if the sensitized corpuscles were suspended in a more alkaline serum. The antibody was found to be thermostable and withstood heating to 56°C for thirty minutes. Complement was required for hemolysis and either fresh human serum or guinea pig serum was satisfactory. The titer of the hemolysin (determined against normal corpuscles under what was thought to be optimum conditions) was 1:8 (final serum dilution).

Absorption experiments showed that normal corpuscles absorbed hemolysin active against patient's corpuscles and vice versa, and there seemed to be no difference in sensitivity to the hemolysin between the patient's immature corpuscles (reticulocytes) and her mature erythrocytes. Repeatedly, the patient's corpuscles were shown to be less sensitive to hemolysis than were normal erythrocytes.

Some of the data on which the above description is based are recorded in table 1.

### DISCUSSION

Although the cause was obscure there can be little doubt as to the nature of the disorder from which the subject of this report was suffering, the negative family history, the severe anemia and high reticulocytosis, the presence of cold hemagglutinins, the positive Coombs test, the relapse after splenectomy and the transient benefit of blood transfusions due to a rapid elimination of the transfused corpuscles, and the presence of an abnormal auto- and isohemolysin in the serum all indicate a severe idiopathic acquired hemolytic anemia.

The presence in the patient's serum of an abnormal hemolysin is the most unusual feature and has seldom been observed. It is probably only in the most severe forms of hemolytic anemia when autoantibodies are being formed in large

(2) Further patient's corpuscles were added to supernatant. The suspension was centrifuged after 30 minutes. Fresh acidified normal serum was added to the deposited corpuscles and the tube incubated at 37°C for one hour. (b) Same as (a) except that normal corpuscles were used throughout. (c) Same as (a), except that normal corpuscles were used in the second stage of the experiment to test for the absorption of the hemolysin by the patient's corpuscles. (d) Same as (a) except that patient's corpuscles were used in the second stage of the experiment to test for the absorption of the hemolysin by the normal corpuscles. **REMARKS** Demonstrates the cross absorption of hemolysin between patient's and normal corpuscles and the relative insensitivity of patient's corpuscles compared with the normal.

\* Serum not acidified (pH approximately 8.0)

† Serum acidified by the addition of 10 per cent by volume of N/4 HCl. The pH after the addition of the corpuscles and incubation at 37°C for 30 minutes was approximately 7.0.

‡ Serum inactivated by heating to 56°C for 30 minutes, acidified with 10 per cent by volume of N/4 HCl after inactivation.

Fresh guinea pig serum was absorbed with equal volumes of washed normal human corpuscles for 30 minutes at 2°C. The serum was used at a final dilution of 1 in 5.

amounts that there is sufficient for detention in the serum over and above that absorbed on to the patient's own corpuscles, this probability, and the fact that adjustment of pH to an optimum for hemolysis is important in the demonstration of hemolysins of the type now described, perhaps accounts for the fact that observations similar to the present have seldom been reported.

In France, however, about forty years ago, the role of hemolysins in acute hemolytic anemia was well recognized (Chauffard and Troisier,<sup>9</sup> Chauffard and Vincent<sup>10</sup>), and these early papers and some others are referred to by Dameshek

FIG. 1.—On the left A (continuous line) a pH hemolysis curve for the hemolysis of normal corpuscles by the patient's (Miss B's) serum and B (interrupted line) the effect of pH on the absorption of the hemolysin; there was only a trace of hemolysis in unacidified serum indicated by the black arrow due to absorption being inhibited by increasing alkalinity.

On the right C (interrupted line) the effect of pH on the absorption of a cold hemolysin present in the serum of a patient suffering from cold hemoglobinuria, and D (interrupted line) the absence of any effect of pH on the absorption of anti A (or anti B) isohemolysins. Curve B is reproduced for comparison.

and Schwartz<sup>11</sup> in their review of acute hemolytic anemia. Following these early papers, however, the association of hemolysins and acute hemolytic anemia seems to have been forgotten until in 1938 Dameshek and Schwartz<sup>12</sup> published 3 cases of their own. More recent reports are those of Farrar, Burnett and Steigman,<sup>13</sup> David and Minor,<sup>8</sup> Neber and Dameshek,<sup>14</sup> and of Ellis, Wollerman and Stetson.<sup>15</sup> Only in the report of David and Minor has the effect of pH on the demonstration of hemolytic activity been investigated. These authors observed a substantial increase in hemolysis when the corpuscles were suspended in serum acidified with 5 per cent N/3 HCl instead of in unacidified serum, in one instance an increase from 47 to 111 mg in the concentration of liberated hemoglobin.

As has already been mentioned, the effects of pH on the action of guinea pig

and human serum complement are well recognized. In the present instance, there was evidence that the absorption of antibody was also controlled by pH, and that it was this effect which was responsible for the comparatively restricted pH range between which hemolysis could be demonstrated.

It was of interest to contrast the behavior of this patient's hemolysin with two other types of antibody, the anti-A and anti-B isohemolysins and a cold hemolysin from a patient suffering from cold hemoglobinuria. The effect of pH on the absorption of these three types of hemolytic antibodies is indicated in figure 1. The left hand curve (A) represents the pH range within which hemolysis of normal corpuscles by Miss B's serum could be demonstrated, the range was

FIG. 2.—The effects of pH on the hemolysis of group A corpuscles by the anti A isohemolysin (curves A) and of group B corpuscles by the anti B isohemolysin (curve B). Curve C indicates the effect of pH on the hemolysis of group O corpuscles by a cold hemolysin present in the serum of a patient suffering from cold hemoglobinuria. The black arrows indicate the amount of hemolysis produced by unacidified serum.

approximately pH 6 to pH 8 with an optimum about pH 7. Curve B represents the effect of pH on the absorption of the hemolysin, i.e., the amount of hemolysis observed when corpuscles sensitized in inactivated serum at a range of pH between 6 and 9 were subsequently resuspended and incubated in fresh normal serum at pH 7.\* The absorption of antibody diminished with increasing alkalinity, and

\* Washed normal erythrocytes were suspended at a final concentration of 5 per cent in volumes of patient's inactivated serum whose pH had been adjusted from 9 to 6 by the addition of 10 per cent by volume of HCl ranging in strength from N/20 to N/2.5 and NaOH ranging in strength from N/20 to N/5. The corpuscle-serum suspensions were centrifuged after thirty minutes at 37°C and the deposited corpuscles washed once in saline warmed to 37°C. Finally volumes of fresh normal serum at pH 7.0 were added to the deposited corpuscles and the tubes incubated at 37°C for 30 minutes. The amount of hemolysis in each tube was dependent upon the amount of hemolysin absorbed in the first stage of the experiment.

it is this fact that probably reduced to a mere trace the amount of hemolysis caused by unacidified serum. In the right hand diagram in figure 1, curve B is reproduced again. Curve C represents the effect of pH on the absorption of the cold hemolysin and the line D shows that pH has no effect on the absorption of anti A (or B) isohemolysin. In figure 2 are shown as a contrast to curve A of figure 1, pH hemolysis curves (the summation of effects of pH on the absorption of the antibody and upon the action of human serum complement) for the hemolysis of normal corpuscles by anti-A and anti-B isohemolysins (curves A and B) and by the cold hemolysin (C). The black arrows indicate the amount of hemolysis produced by unacidified serum at approximately pH 8, and show that this is almost maximal. In the case of curves A and B (fig. 2), the relatively wide range of pH within which hemolysis will take place is due to pH affecting the activity of serum complement alone and not the absorption of the antibody. The range for the cold hemolysin (curve C) is slightly more restricted on the alkaline side, in this case, there is some impairment of absorption of antibody between pH 8 and 9. It is noteworthy that the pH range for the action of Miss B's hemolysin quite closely corresponds to the pH range within which the erythrocytes from patients with nocturnal hemoglobinuria will undergo hemolysis in normal serum (Dacie and Richardson<sup>4</sup>).

It is remarkable that the effect of pH on the activity of the three different types of hemolysins described in this paper was different in each case. Such differences no doubt reflect subtle differences in the composition of the protein complexes concerned. From the practical point of demonstrating the hemolytic nature of these antibodies *in vitro*, the effect of pH cannot altogether be disregarded.

#### SUMMARY

The presence is recorded of an abnormal hemolysin in the serum of a patient with severe acquired hemolytic anemia. Its activity *in vitro* was determined by the pH of the corpuscle-serum suspension, the optimum pH was about 6.8 to 7.0 and there was inhibition above pH 8 and below pH 6. This pH range is contrasted with that of other human serum hemolytic systems, it is similar to that found in nocturnal hemoglobinuria.

# OBSERVATIONS ON THE INFLUENCE OF THE HYPOPHYSIS AND THE ADRENAL CORTEX ON BLOOD PLATELET LEVELS

By ELIJAH ADAMS, M D \*

THE MAMMALIAN blood platelet remains the formed blood element about which there is little significant information. Major areas of ignorance include the factors concerned with the regulation and the mechanism of platelet formation, release, and utilization, as well as with the exact role of platelets in vascular hemostasis and plasma coagulation.<sup>2</sup> The observations described in this paper were planned to examine the hypothesis that the circulating level of blood platelets might be subject to the influence of certain endocrine secretions. Although no clear indication for such a relationship exists, several lines of evidence are consistent with this working hypothesis. First, a variety of stressful stimuli, including fever,<sup>11</sup> severe exercise,<sup>15</sup> anoxia,<sup>16</sup> hemorrhage,<sup>21</sup> trauma<sup>28</sup> and surgery<sup>1</sup> are reported to result in significant elevation of the platelet count. Since such conditions have as one common factor the stimulation of the pituitary-adrenal cortex system,<sup>17-24</sup> it seemed reasonable to evaluate the possibility that these glands exercise a direct influence on the mechanisms determining the level of circulating platelets.

Secondly, much recent work has revealed a relationship between the activity of several endocrine glands and processes of hematopoiesis involving both the red and white cell series.<sup>13</sup> The anemia which follows hypophysectomy<sup>7-19-27</sup> and the control of lymphocytes exerted by the pituitary-adrenal cortex system<sup>1</sup> represent the more clearly established correlations between endocrine secretions and processes concerned with hematopoiesis.

Finally, there is some evidence that hemostatic vascular reactions, believed to involve the blood platelets,<sup>3-28-30</sup> may be altered by endocrine influences. Ungar<sup>29</sup> presented data indicating that the spleen, activated by the pituitary and the adrenal cortex, secretes a substance effective in shortening bleeding time and increasing capillary resistance.

Observations directed specifically toward a possible endocrine influence upon platelet levels are few in number. Estrogens, administered in massive doses over a period of weeks, have been reported to reduce the platelet counts of dogs and monkeys to purpuric levels,<sup>6-8</sup> the final picture being that of an aplastic anemia in which all the cellular components, both of the peripheral blood and bone marrow, were at low levels. Shekiet and associates<sup>22</sup> observed an average increase of 76 per cent in the blood platelets during the terminal postoperative week in adrenalectomized rats. A report by Dalton, Masson and Selye<sup>9</sup> describes a similar steady rise in platelets following bilateral adrenalectomy in rats. The results of sham

operation are mentioned in neither report, however, and the well-substantiated phenomenon of a platelet elevation following all types of surgery<sup>1</sup> makes it impossible to ascribe specifically to the absence of the adrenals the platelet changes reported in these two studies. Zondek and Kaatz<sup>2</sup> reported a moderate reduction in the platelets of men one hour following the administration of small doses of adrenal cortex extract (Richter—cortigen), and an increase following oral thyroid and parenteral thyroxin or thyrotrophic hormone. Following castration of male and female albino rats a significant drop in platelets lasting several months has been described, as well as a gradual elevation of platelets following the subcutaneous injection of gonadal extract.<sup>4</sup>

### MATERIALS AND METHODS

The animals used in this study were male Sprague Dawley rats weighing between 175 and 300 Gm., male and female mice of both the A and the CBA strain between 8 and 12 weeks of age and young adult male rabbits of mixed strain. All animals were kept in air-conditioned rooms at controlled temperatures and fed a standard diet composed of Purina Lab Chow (rats and mice) or Purina Rabbit Chow.

The platelet counting method employed is described in detail elsewhere.<sup>2</sup> In brief the method for rats and mice was as follows: By heart puncture a small standard quantity of blood (0.1–0.2 cc.) was aspirated into a 2-cc. syringe containing a measured volume of sodium oxalate solution. A quantitative dilution of the blood having been made in the original syringe the contents were mixed, transferred to a test tube and allowed to remain undisturbed until a clear layer of diluted plasma appeared as a result of the sedimentation of erythrocytes and leukocytes. This layer was then sampled with a capillary pipet and the platelets counted in a hemocytometer of conventional type. The method for rabbits was identical in essentials except that blood was drawn from the ear artery rather than from the heart. In the case of mice it was necessary to sacrifice an animal for each determination, the heart puncture being performed after opening the chest. Serial counts could be easily made both in rats and rabbits.

Splenectomy and bilateral adrenalectomy were performed on rats and mice in the usual manner under ether anesthesia using a clean but not sterile technic. Following bilateral adrenalectomy mice were given routinely a single subcutaneous injection of desoxycorticosterone acetate in sesame oil (0.25 cc. containing 1.25 mg.), both rats and mice were given a 1 per cent solution of NaCl as drinking water following adrenalectomy. In many but not all cases completeness of adrenalectomy was checked by autopsy.

Male, Sprague Dawley rats, hypophysectomized at about 2 months of age, were obtained from the Hormone Assay Laboratory, Inc., Chicago. Hypophysectomy was considered complete if the animals failed to gain weight and if a marked degree of testicular atrophy appeared.

Aqueous adrenal cortex extract (Wilson) was the preparation of cortical hormone used and was administered to rats subcutaneously in doses of 1 cc. per 100 gm. body weight. Injected control fluids such as physiologic saline and water were given in the same doses. Mice received 0.25 cc. of aqueous adrenal cortex extract subcutaneously; rabbits were given 10 cc. of this preparation subcutaneously.

### RESULTS

#### *Adrenal Cortex Extract in the Intact Animal*

Large single doses of aqueous adrenal cortex extract were found to be without influence on the platelet counts of mice, rats and rabbits. Mice (CBA strain) were sacrificed in groups of 4 to 10 individuals at intervals from fifteen minutes to forty-eight hours following hormone. A group of 16 rats was subjected to platelet counts immediately before, three and twenty-four hours after the injection of adrenal cortex extract. Six rabbits were followed with serial platelet counts at intervals of 1, 4, 8, and 24 hours after hormone. At no interval following injection in any

FIG. 1.—Serial changes in the platelet count following adrenalectomy each point represents the percentage change from the last preoperative count in a given rat.

FIG. 2.—Serial changes in the platelet count following sham adrenalectomy each point has same significance as in figure 1. Note similarity to the response after adrenalectomy in figure 1.

of these species, could consistent, significant differences from the control values be detected

*Adrenalectomy*

Platelet counts were performed serially following adrenalectomy in a group of 25 male Sprague-Dawley rats, and following sham-adrenalectomy in a group of 19 similar animals. Both types of operation were carried out in identical fashion, except that in the control operation a piece of perirenal fat was removed from the vicinity of each kidney without disturbing the adrenal gland. The similarity of the platelet response, both in magnitude and duration, can be seen from inspection of figures 1 and 2. In these figures, each point represents the calculated percentage difference between the platelet count on a particular postoperative day in a given animal, and the preoperative count in the same individual. Additional data, covering only the first five postoperative days, revealed no significant difference in the platelet rise following adrenalectomy and sham-adrenalectomy in mice of the A strain.

*Adrenal Cortex Extract Following Adrenalectomy*

In contrast to the failure of adrenal cortex extract to influence the platelet level of intact rats, comparable doses of hormone given to rats following adrenalectomy were found to produce a consistent reduction in the platelet count as detected by comparing counts made in the same animal immediately before and three hours after administration. Individual values for the per cent reduction in platelet numbers ranged between 9 per cent and 28 per cent, the consistency of the direction of change being more striking than its magnitude. Rats were first examined for platelet changes following hormone administration four or five days after adrenalectomy, and the same rats, in most instances, were used for repeat observations at longer periods—between ten and sixty days—postoperatively. A control group of rats subjected to sham-adrenalectomy and examined five to eleven days following operation, was found to show no consistent platelet response to adrenal cortex extract. It should be mentioned that the group of rats originally used to examine the effects of adrenal cortex extract on platelets in the intact animal was subsequently subjected to adrenalectomy or sham-adrenalectomy for the postoperative trial of hormone, so that with a few exceptions, the same group of individual rats served both as control and experimental animals.

In some, but not all, instances, autopsy was performed on rats allowed to survive for long periods (up to sixty days) after adrenalectomy. In a few of these animals regenerated adrenal tissue was found, and the data discarded. No animal was used in the adrenalectomy series unless removal of both adrenals intact had been accomplished. It was considered that adrenalectomy was functionally complete at the five-day interval, even though adrenal regeneration might have occurred many days subsequently. No adrenal tissue was found in any of a group of 13 rats autopsied five to seven days following adrenalectomy.

In an attempt to control these observations further, comparable doses of physiologic saline were given subcutaneously to a group of adrenalectomized rats on the fifth postoperative day. The unexpected finding was made that in the adrenalectomized, but not the sham-operated rat, this treatment too was followed by a

fall in platelets comparable in magnitude to that observed after administration of adrenal cortex extract. In contrast, distilled water given in similar quantity to a group of adrenalectomized rats was succeeded by no significant change in the platelet count. These data are summarized in table 1.

The unlikely possibility that a reduction in the platelet count of such magnitude might be ascribed to hemodilution in the adrenalectomized rat, brought about by the actual volume of adrenal cortex extract or saline injected, was tested by following the change in hemoglobin\* concentration three hours after the subcutaneous administration of physiologic saline to a small number of rats five days after adrenalectomy or sham-adrenalectomy. Under these conditions, the maxi-

TABLE 1—Comparison of average percent change in the platelet count immediately before and 3 hours after the administration of several different preparations to intact, adrenalectomized and sham-adrenalectomized rats

Operative Group	Material Injected	Number of Animals	Days Postoperative	Percent Change in Platelets 3 Hours After Injection
Intact	Adrenal Cortex Extract	16		+4 ± 2.6

† Values significantly ( $p < 0.01$  by  $t$  test) lower than all other mean values shown. No significant differences between any other two sets of means.

imum reduction in hemoglobin was 7 per cent below the preinjection level, the mean for five animals being a fall of 4 per cent.

### Hypophysectomy

Male Sprague-Dawley rats hypophysectomized at about 2 months of age were followed with serial platelet counts. All counts made within a three week period after hypophysectomy were not included in analyzing the data, because of possible nonspecific effects on the platelet level of the operation itself. As can be seen from table 2, the average value for a group of platelet counts in 23 hypophysectomized rats was significantly, although not strikingly, lower than the average for a group of 71 intact rats of the same sex, strain and approximate age.

\* Hemoglobin was determined in the Coleman Jr Spectrophotometer by the alkaline hematin method.<sup>22</sup>

The phenomenon of a reduction in platelet numbers following the administration of adrenal cortex extract to adrenalectomized rats might suggest the possibility of a similar change in hypophysectomized rats after a postoperative interval sufficient to permit adrenal atrophy. No significant difference was noted, however, between the preinjection and three-hour postinjection platelet counts of a group of 6 rats given subcutaneous adrenal cortex extract twenty-eight days after hypophysectomy.

† Significantly lower than control mean ( $p < 0.01$  by  $t$  test)

#### *Platelet Response to Splenectomy in Intact and Hypophysectomized Rats*

Of all types of surgery, splenectomy is generally followed by the largest and most enduring postoperative elevations in the platelet count.<sup>25</sup> There is some evidence<sup>8</sup> that this phenomenon is due to removal of the large complement of reticulo-endothelial cells in the spleen, which may normally play a role in clearing platelets from the circulation. An alternative explanation holds that the spleen normally exerts an inhibitory effect on platelet formation in the bone marrow, an activity quite clearly demonstrated by Dameshek and Miller<sup>10</sup> in patients with essential thrombocytopenic purpura.

In contrast to the minimal reduction of the platelet count as a result of hypophysectomy, the platelet response following splenectomy was found to be markedly depressed in the hypophysectomized rat as compared with the effects of splenectomy in the intact rat.\* On the fifth and sixth day postsplenectomy in the otherwise intact rat, maximum platelet levels were observed, representing percentage increases roughly 100 per cent above the preoperative level. At a similar interval after splenectomy in hypophysectomized rats, increases averaging about 40 per cent were noted. These data are expressed in figures 3 and 4, in which each point plotted represents the calculated percentage difference between the platelet count in a given rat at the indicated postoperative level and the preoperative count in the same animal.

A small number of intact and hypophysectomized rats, before and five days after splenectomy, were autopsied to provide marrow specimens examined by the method described by Mayer and Ruzicka.<sup>18</sup> This technic permits the microscopic examination of a longitudinal section of the entire femoral bone marrow fixed in

\* Most of the hypophysectomized rats were subjected to splenectomy at least 1 month following hypophysectomy. In 4 rats, splenectomy was performed only eight days following hypophysectomy; no difference in platelet response was observed in this group as compared with the results of splenectomy in the remaining hypophysectomized animals.

FIG 3 —Platelet response to splenectomy in the intact rat each point represents the percentage change from the last preoperative count in a given rat

FIG 4 —Platelet response to splenectomy in previously hypophysectomized rats Each point has same significance as in figure 3

situ, and was thought to be the best method available for enumerating bone marrow elements of infrequent occurrence such as megakaryocytes. The megakaryocytes seen in 20 high-dry fields (magnification 400 diameters) of each bone mar

row section were counted, the results, recorded in table 3, indicate a significant reduction of megakaryocytes in the hypophysectomized rat both before and after splenectomy, but no significant change in the number of megakaryocytes following splenectomy either in intact or hypophysectomized rats. The failure to note quantitative changes in megakaryocytes following splenectomy agrees with the observations of Higgins and Stasney<sup>14</sup> that marrow imprints made following splenectomy in otherwise intact rats revealed no significant increase in the number of megakaryocytes, despite a large postoperative rise in circulating platelets.

Inspection of megakaryocytes in Giemsa-stained smears of the bone marrow of rats in the four categories cited above—intact and hypophysectomized, before and after splenectomy—revealed no qualitative morphologic differences in megakaryocytes, such as depression of platelet formation, absence of granularity, and other changes of the type described by Dameshek and Miller<sup>10</sup> in idiopathic thrombocytopenic purpura of man.

TABLE 3—Bone marrow megakaryocytes in hypophysectomized and intact rats before and 5 days after splenectomy

	Relation to Splenectomy	Number of Animals	Number of Megakaryocytes*

	After	3	75 $\pm$ 4.7

\* Number per 20 high dry fields. Means and standard errors.

† Both hypophysectomized means significantly lower than either intact mean ( $p < 0.01$  by  $t$  test). No significant difference before or after splenectomy in either group.

Other relevant observations included changes in the weight and histologic appearance of spleens removed from hypophysectomized rats. As reported earlier by Perla<sup>20</sup> hypophysectomy is followed by a progressive reduction in spleen weight. In the present study, the spleen/body-weight ratio in rats a month after hypophysectomy was found significantly lower than the same value in intact rats of corresponding age. Histologic changes in the spleens of hypophysectomized rats included the presence of fewer megakaryocytes in this tissue as well as in the bone marrow, and a reduction of mitotic activity in the germinal centers of lymphoid follicles. A fuller account of the morphologic alterations in the spleen after hypophysectomy can be found in Perla's paper,<sup>20</sup> which also describes hyperplasia of the germinal centers of splenic lymph follicles, and an increased number of megakaryocytes, both in spleen and bone marrow, in rats given extracts of dried beef pituitary.

## DISCUSSION

The results described do not support the hypothesis that blood platelets are influenced in any specific or significant way by the hormones of the pituitary or adrenal cortex. The almost exact similarity in response of platelets to sham opera-

tion and to adrenalectomy would seem to confirm the suspicion that those reports describing large increases in platelets after adrenalectomy, were simply observations of the well-known phenomenon of postoperative thrombocytosis seen after major surgery of almost any nature

Of more positive interest, although difficult to relate to other findings, is the observation that the administration either of adrenal cortex extract or physiologic saline is followed by a significant fall in platelets in the adrenalectomized but not in the sham-operated rat. This finding, coupled with the failure of distilled water to influence the platelets of adrenalectomized rats, suggests a possible electrolyte effect, although no further light can be thrown on this question with the data of the present study. Whatever mechanism underlies this observation, the fact that it does not occur in rats some weeks after hypophysectomy suggests that it requires the absence, rather than a moderate relative functional insufficiency, of the adrenals.

Observations of platelet levels following hypophysectomy, and the platelet response to splenectomy of the hypophysectomized rat, raise some interesting questions as to the equilibrium of production and removal rates which must govern the level of circulating platelets. First, the small, if significant, decline in platelets in the hypophysectomized rat, does not by itself suggest any primary action of the pituitary on platelet levels. Changes of this magnitude might be considered part of the picture of generalized tissue atrophy and lowered tissue metabolism following hypophysectomy, just as the reduction of megakaryocytes in the marrow is part of the picture of generalized marrow hypoplasia.

The marked reduction in the thrombocytosis following splenectomy in the hypophysectomized animal, however, suggests an additional possibility. The atrophy of the spleen which occurs after hypophysectomy may quite possibly indicate a reduced functional capacity of this organ, and perhaps other reticulo-endothelial tissue, to remove platelets from the circulation. With such a reduction in level of both platelet-forming and platelet-removing potential, a new equilibrium in the level of circulating platelets might be established, which would not differ greatly from the level in the intact animal. Sudden removal of a large component of reticulo-endothelium, as by splenectomy, might then temporarily unmask the reduced production capacity (by eliminating the balancing factor of platelet removal), and permit its detection in terms of a much depressed platelet response to splenectomy. Such an explanation is of course not uniquely determined by the observed facts, but merely fits them with reasonable simplicity.

#### SUMMARY

Observations were made to investigate possible endocrine influences on blood platelets. Adrenal cortex extract failed to influence the platelet counts of mice, rats, or rabbits. Adrenalectomy and sham-adrenalectomy were followed by almost identical platelet increases in mice and rats. Administration of adrenal cortex extract, or physiologic saline, to adrenalectomized rats was followed by a consistent fall in platelets not observed in sham-adrenalectomized rats, or after administering distilled water to adrenalectomized rats. Platelet levels in hypophysectomized rats were significantly lower than in unoperated controls. Splenec-

tomy in hypophysectomized rats was followed by a maximum rise in platelets markedly lower than following splenectomy in intact rats. Bone-marrow megakaryocytes in hypophysectomized rats were significantly fewer than in intact rats. No changes in megakaryocyte number or morphology appeared following splenectomy either in intact or hypophysectomized rats.

# THE EFFECT OF HUMAN PLASMA TRANSFUSIONS ON THE FECAL UROBILINOGEN EXCRETION IN SICKLE CELL ANEMIA

By EUGENE KAPLAN,\* M D , AND S ROBERT LEWIS, M D

IN 1938, Josephs<sup>1a, b</sup> reported a phenomenon occurring in children with hemolytic anemia fecal urobilinogen excretion was observed to decrease following either blood transfusions, plasma injections or injections of concentrates of human or pig plasma These decreases were of variable degree, occurred within a week of treatment, and lasted up to three weeks Changes in the levels of red blood cells or hemoglobin were slight or absent Infection accompanied by erythroblastosis appeared to interfere with this phenomenon Since the original report, this observation has not been confirmed The present report deals with observations on children with sickle cell anemia in which we have attempted to confirm and study further the presence of an antihemolytic factor in plasma by means of fecal urobilinogen excretion

## METHODS

### *Urobilinogen Determination*

Urobilinogen was determined by the method of Watson<sup>2-4</sup> The total feces for periods of two to four days were collected in cardboard containers tightly covered and stored in a refrigerator The total stool was then thoroughly mixed with water and weighed To a 10 Gm sample was then added 300 cc. distilled water 100 cc ferrous sulfate solution, and 100 cc of 10 per cent sodium hydroxide The resultant mixture was then placed in the dark for at least one hour or until the supernatant solution appeared relatively colorless Occasionally as in the case of specimens with very high urobilinogen content the supernatant fluid appeared distinctly yellow Then 50 cc. of filtrate of the original mixture was added to 25 cc. of 20 per cent ferrous sulfate to which was then added 25 cc of 10 per cent sodium hydroxide This mixture was placed in the dark for one half to one hour, at which time its supernatant fluid appeared relatively colorless Fifty cc of filtrate of the mixture to be used was then removed, placed into a separatory funnel and acidified with 5 cc glacial acetic acid Extraction with 100 cc. of petroleum ether was then performed no less than ten minutes having been allowed for the actual shaking The ether layer was then shaken with Ehrlich's aldehyde reagent followed by shaking with saturated sodium acetate solution The proportion of Ehrlich's reagent to acetate solution was maintained at 1 to 3 This was repeated until no further color developed The total volume of colored solution obtained was measured and the color read in a Klett-Summerson colorimeter using a phenol sulfonphthalein standard Calculation was performed as suggested by Watson Excretion was uniformly expressed as mg urobilinogen per diem average

### *Materials*

The plasma used for therapy was whole plasma For the last 3 transfusions of the 12 administered to Patient I and for all the 4 transfusions administered to Patient V it was obtained from freshly drawn citrated blood of the same blood group as the recipient It was always used within twelve hours All other plasma was derived from Red Cross dried pooled plasma reconstituted just prior to administration

## OBSERVATIONS ON CONTROL SUBJECTS

Urobilinogen determinations were made on a group of 10 control children, either normal or convalescent from some minor illness, and varying in age from 1 year to 12 years. Seven of these patients had two or more determinations. The results conform closely to those reported by Tat, Greenwalt and Dameshek,<sup>3</sup> who used the same technic in infants and children. Urobilinogen excretion varied from 2 mg. to 12 mg. per diem, the amount being roughly proportional to the age and weight of the subject. When expressed as hemolytic index, or mg. urobilinogen excretion for each 100 Gm. estimated total hemoglobin, the resultant values are markedly lower than those observed in normal adults by Miller et al.<sup>4</sup> and also by Watson.<sup>5</sup>

## OBSERVATIONS ON SICKLE CELL ANEMIA SUBJECTS

Urobilinogen excretion was followed in 5 children with sickle cell anemia. The severity and manifestations of the disease were not unusual in these patients who were hospitalized specifically for purposes of this study. The rate of urobilinogen excretion before treatment was at least 5 to 10 times that of the control group, the lowest levels being at least 75 mg. per diem.

## APPARENT CONFIRMATION OF JOSEPH'S HYPOTHESIS

Decreases in urobilinogen excretion were observed in 3 out of 4 cases transfused with whole human plasma, and in 1 infant transfused with the whole blood.

*Case I, A. M.* (Bellevue Hospital #19207-46) a Negro boy aged 10 years was under intensive study for three years. Since the age of 5 he had recurrent attacks of pain in his back and extremities and less frequent mild hemolytic crises. He also had occasional attacks of moderately severe asthmatic bronchitis. The spleen was not enlarged and characteristic roentgenologic changes of chronic hemolytic anemia were present in his skull and phalanges.

Between October 1945 and April 1946 this patient received four plasma transfusions. With the exception of the second one in which only 30 cc. were given and following which stool collections were faulty, each of these was followed by a 50 to 75 per cent decrease in urobilinogen excretion (fig. 1). The effect appeared within five days after treatment and lasted from two to four weeks. There were no significant changes in the levels of hemoglobin, red cells, or serum bilirubin during this entire period.

*Case II, W. M.* (Bellevue Hospital #17381-48) a 10 year old Negro boy was observed for two years. During the previous four years he had been hospitalized elsewhere for annual attacks of abdominal pain, weakness, and icterus and treated with whole blood transfusions. During the present study he remained free of such attacks and had occasional episodes of acute sinusitis. He had moderately severe anemia, icterus and slight splenomegaly.

A single transfusion of human plasma was followed by a decrease in fecal urobilinogen excretion (fig. 4). Pretransfusion excretion was relatively stable. Following the transfusion urobilinogen output decreased 40 per cent and slowly increased to previous levels during the next three weeks.

*Case III, W. D.* (Bellevue Hospital #40130-44) a Negro boy aged 4 years had recurrent attacks of abdominal pain associated with pallor, icterus, and splenomegaly since 1 year of age.

A marked decrease in urobilinogen output followed a single transfusion of plasma. Whereas excretion prior to transfusion fluctuated widely, the decrease afterward was striking, reaching levels of 20 mg. a day, the previous low level was 75 mg. a day. The effect appeared within 5 days and persisted during the next three weeks, terminating suddenly when the patient developed a mild hemolytic crisis.

FIG 1.—UROBILINOGEN EXCRETION CASE I A.M. PERIOD I Vertical axis indicates urobilinogen excretion mg per day Note decreased excretion following transfusions

Case IV C C (Bellevue Hospital #26826-47) a Negro female aged 1 year was hospitalized repeatedly since 6 months of age because of recurrent pallor associated with mild respiratory infections and required monthly blood transfusions. Except for pallor icterus and splenomegaly she was an alert well developed and nourished infant.

Urobilinogen excretion decreased 40 per cent following each of two transfusions of citrated whole blood. This effect appeared within a few days after transfusion and gradually disappeared in the next two weeks.

FIG 2.—UROBILINOGEN EXCRETION CASE I A.M. PERIOD II Vertical axis indicates urobilinogen excretion mg per day Note (1) variable effect following transfusions (2) spontaneous cyclic variations

It is thus clear that in each of these 4 cases we were able to confirm the observation of Josephs that the administration of plasma will induce a temporary reduction in fecal urobilinogen excretion in sickle cell anemia. This reduction was not, however, accompanied by any rise in the levels of hemoglobin or erythrocytes. Its possible significance will be discussed below.

FIG. 1—(Continued)

## REVERSAL OF THE JOSEPHS PHENOMENON

Case I (A.M.) was followed closely for an additional period of twenty months (April 1946 to January 1948), during which time periodic observations were made on the relation of plasma transfusions to the urobilinogen output. A number of

FIG. 3—UROBILINOGEN EXCRETION CASE I (A.M.) PERIOD III. Vertical axis indicates urobilinogen excretion mg per day. Note increased excretion following transfusions.

interesting features arose during this period. There were cyclic variations in urobilinogen output which could not be related to season or infection and were not accompanied by erythroblastosis. There were also mild intermittent attacks of abdominal pain which could not be attributed to increased hemolysis. In December 1946, there occurred a sudden attack of obstructive jaundice with intense icterus, a

direct van den Bergh reaction and clay colored stools, this was associated with fever, leukocytosis, extreme erythroblastosis, and severe abdominal pain. Exploratory laparotomy was considered but was not carried out because of amelioration of the symptoms.

FIG. 4.—UROBILINOGEN EXCRETION CASE II W. M. Vertical axis indicates urobilinogen excretion mg per day. Horizontal axis indicates days. Note decreased excretion following transfusion.

tion of the symptoms. The obstruction was attributed to biliary sand, which has been known to produce occlusion of the bile passages in sickle cell<sup>6</sup> and other hemolytic anemias.

Of the greatest interest during this twenty month period of observation was the

change in the response to plasma transfusions. Nine such transfusions were given during this period. Between May 1946 and February 1947, four transfusions were given which produced virtually no change in urobilinogen output (fig 2). In

FIG 5—UROBILINOGEN EXCRETION CASE V R P Vertical axis indicates urobilinogen excretion mg per day Horizontal axis indicates days Note increased excretion following transfusion

the succeeding period of one year (February 1947 to February 1948), five more transfusions were given. Not only did these fail to decrease urobilinogen output but they actually produced the reverse effect—an increase in its excretion (fig 3). This, too, was not accompanied by any consistent change in the levels of

# THE EFFECT OF QUANTITATIVE AND QUALITATIVE PROTEIN DEFICIENCY ON BLOOD REGENERATION I WHITE BLOOD CELLS

By K. GUGGENHEIM, M D, AND EDITH BUECHLER, M Sc

THE LEVEL of dietary protein has been demonstrated by several investigators to be a factor in the regeneration of leukocytes and granulocytes. The studies of Kornberg et al.,<sup>1</sup> Wright and Skeggs<sup>2</sup> and of Daft<sup>3</sup> have shown, that diets of low protein content produce leukopenia and granulocytopenia, and that this abnormality can be effectively corrected by the administration of proteins or of the ten essential amino acids. Wissler<sup>7</sup> has noted, that protein depleted rabbits and rats exhibit a lowered granulocytic response following infection.

The studies outlined in this paper were carried out for the purpose of obtaining additional information concerning the effect of the level of dietary protein on the regeneration of leukocytes and granulocytes in protein depleted rats. Furthermore, the specific effects of various food proteins on the production of leukocytes and granulocytes were studied.

## METHODS

For the production of leukopenia, male albino rats within one week after weaning were fed a protein-free basal diet which consisted of 91 Gm starch, 5 Gm olive oil, and 4 Gm salt mixture, 0.1 mg thiamine hydrochloride, 0.2 mg riboflavin, 0.1 mg pyridoxin, 1.6 mg calcium pantothenate, 0.25 mg folic acid, and 100 mg choline chloride per 100 Gm ration were incorporated into the diet. Each rat received 100 I U vitamin A and 4 I U vitamin D twice weekly. After being fed on this diet for two weeks, leukopenia and granulopenia were noted in about 75 per cent of the animals. Leukopenia was considered to be present when the white blood cells numbered 4000 or less cells per cu mm, granulocytopenia when the number of granulocytes amounted to 1200 or less per cu mm. The granulocytopenia observed was not caused by secondary folic acid deficiency as in the experiments described by Wright and Skeggs<sup>2</sup> and by Daft<sup>3</sup> since additional supplementation of the diet with this vitamin did not delay the development of the blood dyscrasia. The hematologic data obtained from 55 normal and 100 protein depleted rats selected at random are listed in table 1.

The leuko- and granulocytopenic rats were used for the determination of the effectiveness of different levels of casein and of various food proteins on the production of white blood cells.

In order to test the effect of different levels of dietary protein the diets listed below were used (grams per 100 grams ration).

	C <sub>1</sub>	C <sub>2</sub>	C <sub>3</sub>	C <sub>18</sub>	C <sub>20</sub>
Casein	3	6	9	18	30
Rice starch	88	85	82	73	61
Olive oil	5	5	5	5	5
Salt mixture	4	4	4	4	4

These diets were supplemented with the above mentioned quantities of vitamins.

In the experiments with qualitative protein deficiency the following protein sources were used: egg powder, dried meat, casein, processed soya bean flour, peanut meal, maize flour, wheat flour (white) and gelatin. Egg powder, dried meat, soya bean flour and peanut meal were fat-extracted. The diets were prepared in the following manner: the various protein sources were incorporated in the protein-free

From the Department of Hygiene and Bacteriology, The Hebrew University, Jerusalem

basal diet by replacing an appropriate amount of starch so as to make the protein level of each diet 9 Gm per 100 Gm ration

Total white blood cell and granulocyte counts were made in the usual manner

After the leuco- and granulocytopenic rats were placed on the experimental diets white blood cell and granulocyte counts were carried out on the fourth eighth and fifteenth days respectively. As the numbers of leukocytes and granulocytes after two weeks were almost the same as after one week, the figures of the latter count are omitted

## RESULTS

The effect of quantitative protein deficiency on regeneration of white blood cells. In this series of experiments the effect of various levels of dietary protein on regeneration of leukocytes were studied. Four diets, C<sub>3</sub>, C<sub>6</sub>, C<sub>9</sub> and C<sub>18</sub> were offered *ad libitum* to protein depleted rats. The changes obtained in weight and in total white blood cell and granulocyte counts are shown in table 2.

As can be seen from table 2, low protein diets induced a slight increase only and occasionally a further decrease in leukocyte and granulocyte numbers. Diet C<sub>18</sub>

on the other hand, which contained sufficient quantities of protein, caused in a four day period when given *ad libitum* a considerable increase in white blood cells which reached the normal number after seven days feeding. In the observed decreases and increases of leukocytes, granulocytes participated to a greater degree than lymphocytes and monocytes, the average percentage of granulocytes in total white blood cells decreased with  $C_2$  from 28 to 15, it remained constant (30) with  $C_6$ , with  $C_9$  and  $C_{18}$  slight increases were observed (from 25 to 30 and from 30 to 34, respectively). It seems, therefore, that granulocytes exhibit a greater sensitivity to protein intake than lymphocytes and monocytes. Statistical analysis of the changes in total white blood cells and granulocytes, observed after one week, showed that the casein levels of the four diets employed differed one from another to a highly significant degree (table 3).

TABLE 3—Statistical Analysis of Changes in Leukocyte and Granulocyte Counts Observed after One Week on Specified Diets. Probability that the Differences are due to Chance

Diets compared	Leukocytes	Granulocytes
$C_2$ vs $C_6$	0.01	0.01
$C_3$ vs $C_9$	0.01	0.01
$C_2$ vs $C_{18}$ <i>ad libitum</i>	0.01	0.01
$C_6$ vs $C_9$	0.01	0.01
$C_6$ vs $C_{18}$ <i>ad libitum</i>	0.01	0.01
$C_9$ vs $C_{18}$ <i>ad libitum</i>	0.01	0.01
$C_{18}$ <i>ad libitum</i> vs $C_{18}$ controlled	0.01	0.05
$C_3$ vs $C_{18}$ controlled	0.01	0.01
$C_{18}$ controlled vs $C_{30}$ controlled	0.01	0.0

Since the four above mentioned diets were offered *ad libitum*, the rats receiving the protein low diets ate considerably less than those receiving  $C_{18}$ . The food consumption of the rats fed  $C_3$  amounted to 60 per cent only of that of the rats given  $C_{18}$ . The observed effect of the diets low in casein may, therefore, be due to protein deficiency or to caloric deficiency or to both protein and caloric deficiency. In order to investigate this question the following series of experiments was conducted. One group of rats received  $C_{18}$  with controlled intake, i.e., an amount of food as was consumed by  $C_3$ , a second group was fed a protein rich diet, containing 30 per cent casein ( $C_{30}$ ) also given with controlled intake. These rats received, therefore, the same amount of calories as  $C_3$  and the same quantity of protein as the rats which were allowed to eat  $C_{18}$  *ad libitum*. The results obtained and their statistical treatment are shown in tables 2 and 3.

These tables demonstrate that the increase in leukocyte and granulocyte counts obtained with  $C_{18}$ , given in restricted amounts is considerably lower than that observed with  $C_{18}$  offered *ad libitum*. On the other hand, this diet proved to be statistically significantly superior to  $C_3$ , although there was no difference in the caloric intake of these two groups. Furthermore, the rats receiving  $C_{30}$  in restricted amounts showed a similar response as those receiving the same quantity of protein

( $C_{18}$  *ad libitum*), and a statistically significantly superior response than those receiving  $C_{18}$  in restricted amounts

The latter observation suggests that the amount of protein eaten, and not its level in diet, is important for the regeneration of white blood cells. The highly significant difference in the response between  $C_3$  and  $C_{18}$ , given in restricted amounts, does not contradict this interpretation. In caloric deficiency the organism is forced to divert protein from cell-synthesis to energy production. When the caloric supply is insufficient, it is immaterial to the caloric economy of the animal whether the restricted diet is rich or poor in protein. The decisive role of the protein intake for white cell regeneration is clearly shown by a comparison of the increases reached by  $C_{18}$  and  $C_{20}$ , both given in restricted amounts. Rats receiving  $C_{20}$  exhibit a significantly larger increase of white cells than those fed on the same

TABLE 4.—*The Effect on Increase in Leukocyte and Granulocyte Counts of Diets Containing Various Proteins at 9 per cent Level Given ad libitum to Protein Depleted Rats Means and Standard Errors*

Source of protein	No of rats	Fourth day			Eighth day		
		Weight grams	Leukocytes	Granulo cytes	Weight, grams	Leukocytes	Granulo cytes

Maize	19	1±0 7	340±190	230±108	1±1 1	500±207	340±105

amounts of  $C_{18}$ . It may, therefore, be concluded, that protein intake plays a decisive role in white blood cell regeneration, and that this effect is due to be masked in a protein-high diet ( $C_{18}$ ), when given in insufficient amounts.

*The effect of qualitative protein deficiency on regeneration of white blood cells.* In our second series of experiments the effects of various proteins (egg, meat, peanut, soya, casein, wheat, gelatin, maize—fed *ad libitum* at 9 per cent level) on production of white blood cells in protein depleted rats were compared. The results are shown in table 4.

It follows from table 4, that protein quality as well as quantity determines white blood cell regeneration. Among the food proteins investigated the proteins of egg and meat rank first. Both are similar in this respect, and, given at 9 per cent level, they exhibited an effect similar to that of casein fed at 18 per cent level. Casein, peanut and soy bean protein rank next. It is interesting to note, that peanut protein effects a similar degree of white blood cell regeneration as does soy bean and casein, despite its decidedly inferior effect on growth. Gelatin, wheat and maize proteins are the least effective for white blood cell regeneration as well as in their growth promoting efficiency. The reactions elicited by diets containing

9 per cent of these proteins are similar to those produced by casein at 6 per cent level

Statistical treatment of the differences in mean increases of total white blood cells and of granulocytes, obtained after one week, revealed the following facts

*Total white blood cells* Egg or meat vs each of the other proteins tested differences highly significant (probability of the occurrence of the observed mean difference in a random sample 1 100 or less) Peanut or casein or soya vs wheat or gelatine or maize differences highly significant (probability 1 100 or less) The differences within each of the three groups were not found to be significant

*Granulocytes* Egg or meat vs each of the other proteins difference highly significant (probability 1 100 or less) Peanut vs wheat difference significant (probability 1 20) Peanut vs gelatin or maize difference highly significant (probability 1 100 or less) Soya vs wheat difference not significant Soya vs gelatin difference significant (probability 1 20) Soya vs maize difference significant

TABLE 5—Per cent of Granulocytes and of Lymphocytes and Monocytes in Protein Depleted Rats before and on the Fourth and Eighth Days after Feeding Various Proteins at 9 per cent Level

Source of protein	Protein depleted		Fourth day		Eighth day	
	Granulocytes	Lymphocytes	Granulocytes	Lymphocytes	Granulocytes	Lymphocytes
Egg	32	68	44	56	40	60
Meat	29	71	38	62	38	62
Peanut	28	72	36	64	35	65
Soya	33	67	38	62	37	63
Casein	25	75	28	72	30	70
Wheat	30	70	43	57	40	60
Gelatin	25	75	40	60	36	64
Maize	29	71	32	68	35	65

(probability 1 100) Casein vs wheat or gelatin difference not significant Casein vs maize difference significant (probability 1 50) The difference within each of the three groups were not found to be significant

It is noteworthy, that all proteins tested produced an increase in granulocytes which was accompanied by a relative decrease in lymphocytes and monocytes Details are given in table 5 The data shown in table 5 suggest that granulocytes regenerate more quickly after protein feeding than lymphocytes and monocytes These observations confirm the above mentioned fact that the percentage of granulocytes decreased with  $C_3$ , remained constant with  $C_4$  and increased with  $C_{11}$

#### DISCUSSION

Our results demonstrate that protein deficient diets invariably impair the regeneration of white blood cells in protein-depleted rats Normal regeneration will occur only when diets containing quantitatively and qualitatively optimal proteins are administered A diet, however, containing an optimal level of protein ( $C_{11}$ ), but given in restricted amounts, will not promote optimal regeneration of

leukocytes. In this masked form of protein deficiency food protein is utilized for energy, and is insufficient therefore for purposes of cell synthesis. A similar phenomenon has already been described by Kosterlitz and Campbell<sup>6</sup> studying the effect of protein deficiency on liver cytoplasm as well as in our studies<sup>3</sup> on the effect of protein deficiency on the bacteriocidal properties and phagocytic activity of peritoneal fluid.

The effect of various food proteins on regeneration of white blood cells corresponds, more or less, to their growth promoting efficiency. Only peanut protein seems to be an exception to this rule. Its relative efficiency on white blood cell production was found to be greater than its growth promoting quality. Since the amino acid composition of each protein determines its nutritive value and growth promoting efficiency (Block and Mitchell<sup>1</sup>), it may be concluded, that, generally speaking, the same amino acid makeup is necessary for both white blood cell production and for growth. Experiments designed to study this question further are in progress.

#### SUMMARY

1. The effect of diets, varying in quantity or quality of protein, on white blood cell regeneration was studied in leukopenic rats, the leukopenia having been induced by a protein-free diet.

2. Diets containing different amounts of casein (3, 6, 9 and 18 per cent, respectively), were fed *ad libitum*. At the 3 per cent level, a further decrease occurred of white blood cells, whereas the other three diets initiated a regeneration of leukocytes, its degree being more or less in proportion to the casein content.

3. In experiments with diets containing 18 and 30 per cent of casein, the amount of protein eaten and not its level in diet was the decisive factor in the regeneration of leukocytes. The white blood cell regenerating effect of a diet containing an optimal level of protein, may be neutralized when given in restricted amounts.

4. Diets containing nutritionally inferior proteins, fed at 9 per cent level, also impaired normal regeneration of leukocytes. The white blood cell regeneration afforded by the proteins investigated was found to increase in the following order: maize, gelatin, wheat, casein, processed soya, peanut, meat, egg.

5. In white blood cell regeneration promoted by dietary protein, granulocytes were found to react to a greater degree than lymphocytes and monocytes.

# THE EFFECT OF QUANTITATIVE AND QUALITATIVE PROTEIN DEFICIENCY ON BLOOD REGENERATION II HEMOGLOBIN

By EDITH BUECHLER, M Sc , AND K GUGGENHEIM, M D

SUFFICIENT evidence is present to indicate that the feeding of rats on a diet containing an inadequate amount of protein<sup>9, 11</sup> or lacking one or more of the ten essential amino acids<sup>12</sup> (especially tryptophane,<sup>1, 2, 5, 17</sup> lysine<sup>4, 6</sup> isoleucine,<sup>10</sup> histidine<sup>3, 16</sup> and phenylalanine<sup>8</sup>) will result in the development of a mild to moderate chronic anemia. The problem of the comparative value of diets containing different levels of protein or various commonly consumed dietary proteins for hematopoiesis is raised by the foregoing studies. The present paper reports experiments with rats, designed to determine (1) the effect of various levels of dietary protein on hemoglobin regeneration in protein depleted rats, (2) the role played by various animal and vegetable proteins in enhancing the regeneration of hemoglobin.

## METHODS

For the production of anemia male albino rats weighing 150-250 Gm were fed the protein-free basal diet described in the preceding paper<sup>14</sup> over a period of eight to ten weeks. During this time the weight of the rats decreased by 28 to 35 per cent and a moderate anemia developed. The results of hemoglobin determinations of 50 normal and 100 protein depleted rats selected at random are shown in table 1.

The anemic rats were used for the determination of the effectiveness of different levels of casein and of various food proteins on the formation of hemoglobin.

The diets employed were the same as those described in our preceding paper.

Hemoglobin was determined in the tail blood by using the acid hematin method.

After placing the anemic rats on the experimental diets hemoglobin determinations were carried out on the 11th and 21st days.

## RESULTS

*The effect of quantitative protein deficiency on hemoglobin regeneration.* In the first part of our investigation, diets containing 0, 3, 9, and 18 per cent casein, respectively, were given *ad libitum* to protein-depleted rats. The results obtained after ten and twenty days are shown in table 2.

The table demonstrates that weight recovery as well as hemoglobin regeneration is dependent on the protein content of the diet. The protein-free diet causes a further decrease in weight and in hemoglobin concentration, protein low diets promote slight increases, whereas a diet with a sufficient level of casein causes a quick recovery of weight and a considerable regeneration of hemoglobin. Statistical analysis of the changes in hemoglobin concentration observed after three weeks showed that the differences between the four diets employed are highly significant (table 3).

The differences obtained with the three protein diets are due to the varying amounts of protein eaten and not to a diminished food intake with the low protein diets. Contrary to the findings with young rats, described in our preceding paper,<sup>14</sup>

From the Department of Hygiene and Bacteriology The Hebrew University Jerusalem

adult rats receiving the C<sub>2</sub> diet consumed as much food (about 15 grams per day) as those offered the C<sub>18</sub> diet. In order to test a possible effect that caloric restriction

may exert, we fed to two series of rats our diets C<sub>2</sub> and C<sub>18</sub>, which were given in quantities amounting to 60 per cent only, i.e., 9 grams per day, of the amount of food eaten when offered *ad libitum*. As may be seen from tables 2 and 3 this dietary

regimen, although retarding weight recovery, elicited a similar response in hemoglobin regeneration as the same diets when given *ad libitum*. It seems, therefore, that in caloric deficiency the body utilizes dietary protein first for hemoglobin formation, which evidently has a priority over weight recovery.

In a third experiment, protein-depleted rats were given a 30 per cent casein diet, also in controlled amounts. These animals received, therefore, the same quantity of protein as those given  $C_{18}$  *ad libitum* and the same amount of calories as the rats fed on  $C_{18}$  in restricted amounts. Table 2 shows a marked increase in hemoglobin concentration, whereas the effect on weight recovery proved to be deleterious. It may be that such an ill-balanced diet causes serious disturbances in the protein economy of the body, leading to the observed phenomena. Further studies in this

TABLE 4.—*The Effect of Change in Weight and in Concentration of Hemoglobin of Diets Containing Various Proteins at 9 per cent Level, Given in Controlled Amounts to Protein Depleted Rats*  
Means and Standard Errors

Source of protein	No of rats	11th day		21st day	
		Weight grams	Hemoglobin %	Weight, grams	Hemoglobin, %

Gelatin	14	-16±2.7	-0.2±0.21	-29±3.6	-0.5±0.35

direction are in progress. Comparing the effect of this diet to those of  $C_{18}$ , given either *ad libitum* or in restricted amounts, it will be seen from table 3, that  $C_{30}$  given in restricted amounts causes a smaller increase of hemoglobin concentration than  $C_{18}$ , the difference between  $C_{30}$  and  $C_{18}$  given *ad libitum*, however, was found to be statistically significant, thus again showing that restriction of the amount of food protein interferes more seriously with the regeneration of hemoglobin than restriction of calories.

*The effect of qualitative protein deficiency on hemoglobin regeneration.* In the second part of our study the effects of various food proteins (egg, meat, processed soya, casein, peanut, maize, wheat, gelatin) on hemoglobin regeneration were compared. Because the rats receiving gelatin, peanut, wheat and maize proteins are considerably less than those receiving the other proteins, the food intake of all rats was equalized and restricted to 9 grams per day. The results obtained after ten and twenty days are tabulated in table 4.

As can be seen from table 4, the different food proteins tested exert different effects on hemoglobin formation. The most effective proteins are those of eggs, meat and soya, in three weeks they elicit an increase of 2 per cent or more in hemoglobin concentration and at 9 per cent level they are as effective as casein at 18

per cent level Casein, peanut and maize proteins rank next. With these proteins increases of 1.3 to 1.5 per cent were observed. The least efficacious proteins were found to be those of wheat and gelatin. They cause a negligible increase only and sometimes a decrease in hemoglobin concentration. The effects of the various food proteins on hemoglobin regeneration correspond, more or less, to their effects on weight recovery. Only casein and soya represent exceptions, the former was found to be more potent in promoting weight recovery than hemopoiesis whereas soya protein was found to be more efficient with respect to hemoglobin formation than in its weight regaining capacity.

### DISCUSSION

The foregoing results indicate that diets containing insufficient amounts of protein will not support normal weight recovery and hemoglobin regeneration in

TABLE 5—*The Relative Values of Various Food Proteins for Regeneration of Hemoglobin and of Granulocytes, Egg Proteins Assumed to be 100*

Source of protein	Regeneration of	
	Hemoglobin	Granulocytes
Egg	100	100
Meat	92	99

Peanut	54	47
Maize	54	18
Wheat	17	27
Gelatin	—2.1	26

protein-depleted anemic rats. Furthermore, low caloric intake, sufficient to suppress normal weight recovery, causes no reduction in the formation of hemoglobin. These findings confirm those of other authors made with different experimental techniques. Albanese et al.,<sup>1</sup> who fed normal rats on low caloric diet sufficient to inhibit growth, did not observe a reduction of hemoglobin concentration. Whipple<sup>14</sup> and Whipple, Miller and Robschert-Robbins<sup>15</sup> studying hemoglobin regeneration in dogs made anemic by the withdrawal of blood, concluded that hemoglobin stands apart in the protein economy of the body in that it does not contribute freely to the protein pool, as do other tissue proteins. Under conditions of protein fasting the body will give up large amounts of protein from its organs to produce hemoglobin, which has a priority over the tissue and organ proteins.

The comparative value of dietary proteins for hemopoiesis in the rat has already been studied with some proteins by Orten and Orten.<sup>12</sup> At an 18 per cent protein level, casein, lactalbumin, dried skim milk, and a mixture of dried skim milk and dried beef blood proved to be of about the same value, both for hemoglobin maintenance in the growing rat and for hemoglobin regeneration in the adult animal. On the other hand, dried beef blood proteins were found to be inferior. In our experiments in which the different proteins were fed at 9 per cent level we found

considerable differences in the hematopoietic values of the eight proteins investigated

The nutritive value of each protein tested is not the same for production of hemoglobin and of granulocytes, as can be seen by comparing the results of the present two studies. Assuming the relative value of egg proteins, as obtained after three weeks for hemoglobin and after one week for production of granulocytes, to be 100, the relative values of the proteins tested can be seen in table 5.

It follows from table 5, that the nutritional values of casein and soya and maize proteins are considerably higher for hemoglobin formation than for production of granulocytes, whereas those of wheat protein and gelatin are much lower.

### SUMMARY

1 The effect of diets, varying in quantity or quality of protein, on hemopoiesis was studied in protein depleted and anemic adult rats.

2 In experiments with diets containing different amounts of casein (0, 3, 9 and 18 per cent, respectively), and fed *ad libitum*, it was found that with a protein free diet a further decrease of hemoglobin occurred, whereas the other three diets initiated a regeneration of hemoglobin, its degree being more or less proportional to the casein content.

3 In experiments, in which diets with 9 and 18 per cent of casein, respectively, were given in restricted amounts, it was found that the degree of hemoglobin formation was similar to that with the same diets when given *ad libitum*, whereas the weight gain was considerably less. It is concluded, therefore, that in caloric deficiency hemoglobin formation has a priority over weight recovery.

4 A diet containing 30 per cent casein and given in restricted amounts induced a further weight loss, whereas the concentration of hemoglobin showed a marked increase. Comparing the results obtained by this diet with those observed with 18 per cent casein diets, given either *ad libitum* or in controlled amounts, it was evident that restriction of the quantity of food protein interferes more seriously with hemopoiesis than restriction of calories.

5 Diets containing nutritionally inferior proteins fed at 9 per cent level, also impaired normal hemopoiesis. Hemoglobin regeneration induced by the proteins investigated was found to decrease in the following order: eggs, meat, processed soya, casein, peanut, maize, wheat, gelatin.

6 Comparing the nutritive value of various proteins for regeneration of hemoglobin and of granulocytes it was found, that casein and soya and maize proteins are considerably more efficient for hemoglobin formation than for production of granulocytes, whereas wheat protein and gelatin have a higher granulocytopenic capacity.

## HYPOPLASTIC ANEMIA DUE TO ATABRINE

B<sub>3</sub> ALFRED P. FISHMAN, M D , AND J. MURRAY KINSMAN, M D

IT IS the purpose of this paper to present the clinical picture which may follow the prolonged ingestion of atabrine. This picture is characterized by a severe anemia which may or may not be associated with a characteristic dermatitis. The dermatitis has been previously described<sup>1-6</sup>, the anemia warrants further consideration. Custer,<sup>7</sup> basing his conclusions on an analysis of biopsy and autopsy material forwarded from the southwest Pacific to the Army Institute of Pathology, indicated atabrine as the agent responsible for the production of the hypoplastic anemia in the cases he reviewed. His report, based on pathologic data, by its very nature stresses the gravity and the poor prognosis of the illness. However, our experience indicates that a more optimistic approach is warranted. We are reporting the pertinent data regarding 7 patients who developed anemia following the prolonged ingestion of atabrine for malarial suppression while serving in the southwest Pacific area. Four suffered a concomitant dermatitis (fig. 1). The majority recovered. This group of patients illustrates the course and prognosis of hypoplastic anemia due to atabrine.

Hypoplastic anemia indicates a disorder of the bone marrow characterized by diminished hematopoiesis. The anemia fails to respond to the usual methods of therapy other than whole blood transfusion. The degree of anemia is variable; leukopenia and granulocytopenia are invariably present. Thrombocytopenia is usually marked and is responsible for hemorrhagic phenomena. The bone marrow varies histologically in architecture, degree of cellularity and maturity.

### CLINICAL MATERIAL

Seven patients with hypoplastic (refractory) anemia were admitted to Moore General Hospital, a tropical disease center. In each instance the anemia was so severe as to require frequent transfusions of whole blood. Each patient exhibited hemorrhagic phenomena. All had spent several months in the southwest Pacific area, but their military itineraries within the area showed little duplication. Only 2 had served in the jungles. One was a nurse, one a Medical Officer, and the others were enlisted men in combat units. Six were white and one was a Negro. All had taken atabrine for many months. Final hospitalization was occasioned by the development of symptoms of anemia in two instances, the appearance of a skin eruption in four, and diarrhea and acute otitis media in one. Details are presented in table 1.

### ETIOLOGY

It is indicated in table 1, that 4 of the 7 patients were hospitalized primarily for dermatitis. This was either of a lichenoid (fig. 1) or an eczematoid type. It has been established that these lesions, as seen in patients from the Pacific area, are caused

From the Medical Service, Moore General Hospital, Swannanoa, N. C.

by prolonged atabrine therapy.<sup>16</sup> This form of dermatitis was not observed in natives or white residents who had never taken atabrine. Moreover, the dermatitis ceased to progress or disappeared entirely after atabrine was discontinued. In case 1 of this series (fig. 2), both dermatitis and a mild anemia appeared while the patient was in the southwest Pacific area. Upon his return to the United States he

TABLE 1—*History of Antecedent Drug Ingestion and Primary Reason for Hospitalization in 7 Cases of Refractory Anemia*

Case	Atabrine history	Reason for final hospitalization	Other drugs prior to onset of anemia
1—M. W. 33 infantryman	0.1 Gm daily for 7 mos none for 11½ mos except for 2 courses of 5 and 7 days each then 0.1 Gm daily for 3 mos when anemia appeared	Anemia	Sulfadiazine 18 mms and penicillin 12 mms previously
2—M. W. 26 infantryman	0.1 Gm daily for 14 mos when dermatitis appeared 6 weeks later anemia first discovered	Dermatitis (lichen planus)	None
3—M. W. 26 infantryman	0.1 Gm daily for 4 mos none for 2 mos 0.1 Gm daily for 6 mos none for 8 mos 0.1 Gm daily for 2½ mos 6 weeks later anemia first discovered	Anemia	None
4—M. W. 37 mechanic	0.1 Gm daily for 11 mos Discontinued because of dermatitis 3 mos before detection of anemia	Dermatitis (lichen planus)	None
5—F. W. 28 nurse	0.1 Gm daily for 18 mos Discontinued because of dermatitis 1 mo before detection of anemia	Dermatitis	Penicillin
6—M. W. 47 medical officer	0.1 Gm daily for 11 mos Discontinued upon evacuation to U S 7 days before detection of anemia	Recurrent diarrhea cause undetermined and acute Otitis Media	Sulfadiazine 6 Gm. daily for 9 days (4 mos before admission). Carbarsone 1.5 Gm for 1 day (4 mos before admission)
7—M. C. 32 infantryman	0.1 Gm daily for 8 mos Discontinued because of dermatitis 1 mo before detection of anemia	Dermatitis	None

discontinued taking atabrine and both the anemia and the dermatitis disappeared. Later, while still in the United States, he resumed atabrine medication for the suppression and treatment of recurrent malarial attacks; a severe anemia and dermatitis resulted. The anemia was ameliorated and the dermatitis improved by discontinuing atabrine.

It should be emphasized that the duration of atabrine therapy appeared to be the determining factor. Experience with the atabrine dermatides demonstrates that the drug must be ingested for comparatively long periods of time to produce

the eruption. In experiments which were done to reproduce the skin lesions it was found that they recurred only after the drug had been taken for several weeks.<sup>4</sup> In all 7 cases reported here, the patients had taken the drug for many months. The effect of the drug has been ascribed to idiosyncrasy, in an experimental study

FIG. 1.—CONCOMITANT (LICHENOID) DERMATITIS

by Parmer<sup>9</sup> no correlation could be established between the concentration of atabrine in the various blood cells and the cells predominantly affected by the hypoplastic anemia.

#### CLINICAL AND HEMATOLOGIC DATA

In table 2, the clinical and hematologic data are tabulated. It will be noted that in each instance anemia was present at the time of original examination, it was usually severe, although in one case (case 5) it was mild. The color index was

FIG. 2.—THE COURSE IN CASE 1.

usually above one. Macrocytosis was the rule. The volume of packed cells (hematocrit) was uniformly low. Leukopenia was invariably present with the polymorphonuclear percentage usually low. The thrombocytes were always below

TABLE 2.—*Clinical and Hematologic Status*

Case	Symptoms of bone marrow alteration	[Initial Hemogram]							Bone marrow early in disease
		RBC	Hgb (Sahli)	Cell vol	WBC	P	Platelets	Retic	
		mill	%			%		%

40,000 per cu mm. With one exception, the reticulocyte count was less than 1 per cent, this patient recovered rapidly. Bone marrow studies were done on 6 patients: in 2 the examination was found to be normal, in 2 normal except for the absence of megakaryocytes, and in 2 there was marked hypoplasia of all elements.

In addition to the data incorporated in table 2, certain additional information is available. Fever was invariably present but was usually not marked. The spleen was barely palpable in only one instance, the lymph nodes were enlarged in two patients and at autopsy were described as hemolymph nodes. In only one patient was the coagulation time prolonged but the bleeding time was always prolonged. The tourniquet test was positive in all cases at the height of the illness. In every instance there was defective clot retraction. There was no evidence of increased

TABLE 3—*Therapy and Clinical Course*

Case	Therapy	Clinical Course	Outcome
1	Transfusions diet liver mash liver extract orally and hypodermically folic acid iron	Frequent hemorrhages from gums throat and nose gradually decreasing. Slow but steady improvement.	Recovered
2	Transfusions diet liver extract orally and hypodermically iron	Moderate steady reticulocytosis persisting when medication was discontinued.	Recovered
3	Transfusions diet liver extract orally and hypodermically iron sternal marrow transplant	Frequent hemorrhages from gums and throat which became uncontrollable hematuria purpura.	Died
4	Transfusions diet liver extract orally and hypodermically iron ascorbic acid hypodermically	No response for a long time. Later reticulocytosis to 10% following liver intramuscularly and maintained by liver mash by mouth. Then gradual improvement temporarily interrupted by homologous serum jaundice.	Recovered
5	Transfusions diet liver extract orally and hypodermically iron penicillin	Gradual improvement. Slow reticulocyte response not related to therapy.	Recovered
6	Transfusions diet liver extract hypodermically	Persistently downhill in spite of transfusions. Death following mastoiditis and acute endocarditis ( <i>Paracolon bacillus</i> ).	Died
7	Transfusions diet liver extract hypodermically penicillin pyridoxine	Hemorrhages stopped after first transfusion but no change in leukocyte or platelet deficiency. Death from staphylococcus (hemolytic) septicemia.	Died

\* Diet: High liver, high carbohydrate, high protein, high vitamin. Iron: Ferrous sulfate orally.

hemolysis. In 6 patients, gastric analysis was done and in no case was achlorhydria demonstrated.

In 4 patients, a skin eruption was present when the anemia was first detected. One patient was originally hospitalized because of severe diarrhea and acute otitis media but hemorrhagic phenomena quickly supervened and became the predominant symptom.

#### THE THERAPY AND CLINICAL COURSE

The broad outlines of the therapeutic program and the clinical course are summarized in table 3. Four of the 7 cases eventually recovered and 3 died. 2 of the deaths were attributed to intercurrent infection and one to uncontrollable bleeding.

Repeated transfusions of whole blood were necessary to tide the patient over the acute phase of the disease. No other therapeutic measure afforded relief from the manifestations of bone marrow depression. Figure 2 is a reproduction of the course of Case 1. The various measures and their hematologic effects are graphically portrayed. None of the therapeutic agents seemed to influence the course of the illness. Whole blood administration, when effective, was only transiently palliative.

#### COMMENT

The mechanism of bone marrow depression by atabrine is complicated by the demonstration that atabrine may remain in body tissues after the drug has been discontinued.<sup>8</sup> Consequently, two factors may cause development of the hypoplastic marrow due to atabrine: (1) the initial cumulative depression due to ingestion of the drug and (2) the perpetuation of the depression by residual stores of drug within the body. Recovery is spontaneous and gradual, apparently uninfluenced by medication.

#### SUMMARY

Seven patients with severe hypoplastic anemia were studied at an army Tropical Disease Center. Four of the 7 patients had concomitant dermatitis. The relationship of the prolonged administration of atabrine to the anemia and dermatitis is presented. A hematologic remission could not be induced by specific therapeutic measures. Four of the 7 cases recovered spontaneously.

#### ACKNOWLEDGMENT

The authors are indebted to Miss Mary L. Boyd for her painstaking supervision of the hematologic studies.

# INFLUENCE OF FIBRINOGEN CONCENTRATION UPON PLASMA PROTHROMBIN TIME

By MURRAY WEINER, M D , AND SHEPARD SHAPIRO, M D

ESTIMATION of the prothrombin time of whole and diluted (12.5 per cent) plasma has been shown to have advantages over the usual one-stage procedure in which whole plasma alone is employed.<sup>1a, b</sup> Recently, Deutsch and Gerarde indicated that the prothrombin time of diluted plasma may be influenced by variations in the fibrinogen level.<sup>2</sup> Their study was on rabbit plasma. In the present communication, data are given concerning the fibrinogen concentration in human plasma in the presence of changes in diluted (12.5 per cent) plasma prothrombin time.

The following studies were made: Simultaneous estimation of prothrombin time and fibrinogen concentration of plasma in (1) normal subjects, (2) cases of hyperprothrombinemia,<sup>3, 4</sup> (3) cases of hypoprothrombinemia.

## METHODS

Estimation of the prothrombin time was made by the procedure previously described.<sup>1a</sup> Fibrinogen concentration was established by determination of the nitrogen content of plasma before and after the contained fibrinogen was coagulated and removed according to the method described by Peters and Van Slyke, modified for micro-kjeldahl technique.<sup>13</sup>

## RESULTS

In the tables given below, the prothrombin time of the diluted (12.5 per cent) plasma is given in seconds. The normal standard is 39.5 seconds, standard deviation  $\pm 2.5$ . (The whole plasma prothrombin time plays no part in the present discussion.) The fibrinogen values are given in milligrams per 100 ml.

Figure 1 is a scatter diagram of 76 simultaneous determinations of plasma fibrinogen and diluted plasma (12.5 per cent) prothrombin time. There is no correlation between the two.

Table 1. In 4 normal persons, simultaneous prothrombin time and fibrinogen estimations were made. The prothrombin time was normal in each case. The fibrinogen values also were normal. In 3 cases of spontaneous hyperprothrombinemia, the fibrinogen results were within the normal range.

Table 2. Normal persons and cases of liver disease were given large doses of synthetic vitamin K intravenously. Each type of response is represented. Prothrombin time unchanged, reduced, or increased. All of the fibrinogen values were within normal limits and no parallelism was observed between the shift in the prothrombin time and the fibrinogen levels.

From the Third (New York University) Division, Goldwater Memorial Hospital, Welfare Island, N. Y., and the Department of Medicine, New York University College of Medicine.

Aided by a grant from the Blood Transfusion Association of Greater New York.

## DISCUSSION

The study was made in normal, hyperprothrombinemic (both spontaneous and induced) and hypoprothrombinemic bloods. Correlation between fibrinogen concentration and variations in prothrombin time is strikingly lacking. All the fibrinogen values are within the normal range while the prothrombin times extend

FIG. 1—Scatter graph representing the fibrinogen concentration and diluted (12.5%) plasma prothrombin time of 76 samples of blood. The series includes cases in which the prothrombin time is normal, prolonged (hypoprothrombinemia) and reduced (hyperprothrombinemia).

TABLE 1—Simultaneous Determinations of Plasma Fibrinogen and Diluted (12.5%) Plasma Prothrombin Time in 4 Normal Subjects and in 3 Cases of Hyperprothrombinemia<sup>2</sup>

Case	Prothrombin Time	Fibrinogen
	sec	mgm per 100 ml

G. Spontaneous hyperprothrombinemia	35.4	430

throughout the gamut of normal, increased and reduced activity. Especially instructive is the contrast between Case H and Case J. In the former, the serial prothrombin time estimations remained within the normal range despite an increase in fibrinogen content from 246 to 609 mg per 100 ml plasma. In Case J, a significant prolongation of prothrombin time occurred simultaneously with elevations in

fibrinogen values from 240 (at which time, the prothrombin time was normal) to 410 mg, when it was definitely at a hypoprothrombinemia level. Case I is likewise noteworthy, because in it, the fibrinogen concentration showed practically no

\* Seventy six mg of synthetic vitamin K (2-methyl-1,4-naphthohydroquinone diphosphoric acid ester tetrasodium salt [Synkayvite]) was given intravenously on each of the first four days. Blood for prothrombin time and fibrinogen estimation was withdrawn each day before administration of the daily dose of vitamin K.

alteration at the time the prothrombin time became reduced to the hyperprothrombinemia range.

Deutsch and Gerarde,<sup>2</sup> working with rabbit plasma, induced in vitro a reduction of the prothrombin time of 10 per cent plasma from 33 seconds to 22 seconds by

adding 150 mg of beef fibrinogen per 100 ml plasma. They pointed out that there was considerable species variation in this effect. Our findings indicate that the results obtained with rabbit plasma are not applicable to man. The normal range of fibrinogen content of the human plasma is 200–600 mg per 100 ml. If fibrinogen variations had as great an effect on human diluted plasma as is implied by the data on rabbit plasma referred to above, it is difficult to understand how the mean prothrombin time of the diluted (12.5 per cent) plasma of 39.5 seconds, obtained by studying blood from several hundred normal subjects, could have a standard deviation of only  $\pm 2.5$ . This fact substantiates further the belief that the usual fibrinogen range of diluted (12.5 per cent) plasma in man (30 mg to 75 mg per 100 ml) does not alter significantly the accelerated clotting time.

Data offered by Owren<sup>7</sup> in his extensive study of the coagulation mechanism support the above conclusion. Owren demonstrated that the critical low level of fibrinogen below which clotting time increases sharply, varies with the prothrombin concentration. In 10 per cent plasma, the fibrinogen concentration must be reduced to below 20 mg per 100 ml before a significant effect upon accelerated clotting time is noted. It is at this dilution that the quality of the clot becomes poor and difficult to detect. The 12.5 per cent plasma yields a firm and easily discernible clot. The 8 per cent plasma often gives a rather poor clot. The range between these two dilutions, 12.5 per cent and 8 per cent, includes the critical fibrinogen concentration below which clotting time rises sharply. This is consistent with our experience of two instances in which 12.5 per cent plasma yielded poor clots and the fibrinogen concentrations were 100 mg per cent and 120 mg per cent. Thus, only in these very rare cases of hypofibrinogenemia (below 150 mg per cent) does fibrinogen concentration become a factor in 12.5 per cent plasma prothrombin time determination. It appears that a poor clot, which is a rare occurrence, may be considered as a warning that the fibrinogen level is sufficiently low to cause an alteration in the accelerated clotting (prothrombin) time.

An obvious modification of the technic would be to use fibrinogen solution as diluent in place of normal isotonic saline. This has been done by Thordarson<sup>8</sup> and by Link and his students.<sup>9</sup> In man, it has been our experience that the prothrombin time of diluted (12.5 per cent) plasma may be affected in an unpredictable fashion thereby. In some instances, the prothrombin time remained unaltered, while in others it became extended. When the protein solution is used as diluent additional factors such as questionable purity and stability may be introduced. These additional variable factors do not exist if saline is used as diluent.

The data presented show considerable difference in fibrinogen concentration with no corresponding variations in prothrombin time. Reliable estimations of the diluted (12.5 per cent) plasma prothrombin time can be made at the low normal level of fibrinogen (180 mg per 100 ml) as well as at the high level of 650 mg per 100 ml.

It has been found by Foster and Whipple,<sup>10</sup> and later emphasized by Link,<sup>9</sup> that fibrinogen is a very labile plasma protein and fluctuates readily in response to a variety of factors. It is important to point out that massive doses of dicumarol may depress the fibrinogen level of plasma<sup>11</sup> but that at therapeutic dosage levels of

dicumarol the fibrinogen concentration is maintained within the normal range. This has been demonstrated in animals<sup>9</sup> and in man.<sup>12</sup>

### SUMMARY

The effect of the normal variations of fibrinogen concentration (180 mg per cent to 650 mg per cent) on the diluted (12.5 per cent) plasma prothrombin time in man, as observed in this study, is not significant.

## BLOOD COAGULATION AND HEMORRHAGIC DISEASE

CIRCULATING ANTICOAGULANTS A TECHNIQUE FOR THEIR DETECTION AND CLINICAL STUDIES C. L. Gailly  
R C Hartmann and W I Morse II From the Clinical Microscopy Division, Department of Medicine  
The Johns Hopkins University and Hospital Baltimore, Md Bull Johns Hopkins Hosp. 54  
255-268 1949

A test for circulating anticoagulants is described utilizing the effect of platelet free plasma on normal blood. The preparation of the platelet free plasma depends on scrupulous technic: siliconed syringes, test tubes and pipets; handling the blood at low temperatures and two separations by centrifugation at 7000 and 12 000-14 000 rpm. By this method amounts of added heparin as low as 0.001 mg per ml platelet free plasma were detectable. In clinical studies eight instances of a circulating anticoagulant were detected. In only one did the addition of toluidine blue suggest the presence of a heparin-like substance. In 9 cases of thrombocytopenia the anticoagulant assays were negative. These interesting studies point up the probability that circulating anticoagulants are probably present much more commonly than suspected in the past and the suggested technic offers another approach to the study of hemorrhagic diatheses. From the standpoint of widespread use the meticulous technic necessary for the successful preparation of platelet free plasma unfortunately is a limitation on its general availability.  
W N V

HUMAN PROTHROMBIN QUANTITATIVE STUDIES ON THE PLASMA LABILE FACTOR AND THE RESTORATIVE EFFECTS OF NORMAL HYPOFIBRINOGENEMIC AND HEMOPHILIC PLASMA ON THE PROTHROMBIN OF STORED PLASMA B Alexander and A de Vries From the Medical Research Laboratory Beth Israel Hospital and the Department of Medicine Harvard Medical School Boston Mass J Clin Investigation 21  
24-31 1949

The conclusions of Loomis and Seegers (Am J Physiol 148 563 1947) namely that deterioration of fibrinogen accounts for lengthening of the prothrombin time in stored plasma and that reactive fibrinogen is necessary for prothrombin activity measured by the one stage technic have been tested by the authors of this report employing as a reagent afibrinogenemic plasma from a subject with spontaneous fibrinopenia. Inasmuch as the retarded prothrombin time of stored plasma was fully restored upon the addition of this plasma it is concluded that fibrinogen is not the factor whose deterioration is responsible for the alteration in the clotting properties of stored blood a conclusion that is further substantiated by the restorative properties of normal plasma rendered fibrinogen free by means of thrombin. This factor (labile factor) which is also present in  $\text{BaSO}_4$  plasma (prothrombin free) as well as in hemophilic plasma is required in adequate amount for normal prothrombin activity. It is pointed out that the use of prothrombin free ( $\text{BaSO}_4$ -treated) plasma containing not only the labile factor but also fibrinogen and antihemophilic activity in normal amounts is preferable to saline as a diluent in the performance of the one-stage prothrombin test since a reduction of the concentration of these important non prothrombin constituents is thereby avoided.

LES DIVERS GROUPES DE SUBSTANCES SYNTHÉTIQUES DOUÉS D'UNE ACTIVITÉ ANTIVITAMINIQUE K ET LA SIGNIFICATION BIOLOGIQUE DES RÉSULTATS OBTENUS (DIFFERENT COMPOUNDS WITH ANTI K ACTIVITY AND THE SIGNIFICANCE OF THE RESULTS OBTAINED) *C. Mentzer* Laboratoire de Chimie Biologique Faculté des Sciences Lyon Bull Soc Chim Biol 30 872-884 1948

A study was made by Mentzer to determine the relation between the chemical structure of various compounds similar to dicoumarol and their anticoagulant activity. His conclusions are similar to those of Link and his collaborators, but whereas the American authors believe that the B cycle is necessarily an hydroxy 4 pyrone 1,2. Mentzer estimates that other cycles such as thiopyrone, quinon, pyridin, cyclo-pentanedione are able to coöper to the molecule the same activity as the B pyronic cycle. In conclusion all the active compounds have the same structure which can be schematized as follows:

$X = (\text{CO}-\text{O}) \text{ or } (\text{CO}-\text{NH}) \text{ or } (\text{CO}) \text{ or } (\text{S})$

If R is an atom of chloride or of hydrogen or a complex of at least 6 carbon atoms the molecule behaves as an antivitamin K. All the compounds also have in common the O atom in B; this O atom can belong to an enolic or ketonic group but the blockage of this oxyhydride function suppresses the activity.

ACQUIRED AFIBRINOGENEMIA IN PREGNANCY *W C Maloney, W J Egan and A J Gorman* From the Medical and Obstetrical Services, St Elizabeth's Hospital, Boston, Mass. New England J Med 240 596-598 1949

This interesting case report describes a hemorrhagic diathesis in a pregnant woman at term, characterized by a critical decrease in fibrinogen. By use of blood transfusions and fraction I of Cohn it was possible to remove a dead fetus surgically after which rapid recovery of the mother occurred. The authors discuss the possible role of fibrinolysis in this type of acquired afibrinogenemia.

C A F

FIBRINOLYSIS AND THE FLUIDITY OF THE BLOOD POST MORTEM *R H Mole* From the Radcliffe Infirmary, Oxford England J Path & Bact 60 413-427 1948

The finding of fluid and incongluable blood at autopsy is not an uncommon occurrence. However, the explanation of this phenomenon has not been subject to critical investigation and it is for this reason that the present study was undertaken. Blood was obtained from the heart and great vessels of 61 cadavers at routine but not consecutive autopsies. Observations on the fibrinolysis in supernatant serum were made by using a modification of Macfarlane's method (1937). A regional difference in the rate of spontaneous intravascular coagulation as well as in fibrinolytic activity was found. Cadaver fibrinolysis is nondialyzable, precipitated at neutral pH in 50 per cent saturation of ammonium sulphate and its activity is destroyed by pepsin. It appears to be a globulin. The appearance of fibrinolysis seems to be part of the body's general reaction to injury and it is probably produced by endothelium.

O P J

CAUSE AND SIGNIFICANCE OF SEASONAL VARIATIONS IN THE HAEMORRHOIC TENDENCY IN THE NEWBORN *E Kerpel-Fronius, F Varga and E Kutas-Pal* From the University's Children's Clinic, Pecs, Hungary Arch Dis Childhood 23 87-89 1948

In a study of 10,000 newborn children over a period of five years, the authors found a seasonal variation in the incidence of melena, cerebral hemorrhage, and cephalhematoma. The peak period was identical for each and occurred during winter and spring, with diminution during summer and autumn. Since the trauma of delivery presumably did not have a seasonal variation, an explanation for the incidence variations was sought in possible changes in the clotting mechanisms and in the capillary fragility.

The most marked prothrombin reductions, the authors state, have been noted (in the literature) to occur in the winter and spring. No other defects of clotting mechanism were known to be of seasonal incidence.

The authors tested capillary fragility in 233 healthy children at various times of the year using both positive and negative pressure methods, and found that the incidence of increased capillary fragility increased in winter and spring, diminished in summer and was minimal in late summer. In addition they noted that conjunctival petechiae in the newborn which are supposedly due to rupture of capillaries during labor were most numerous in spring and winter. There was thus a distinct parallelism in incidence of cerebral hemorrhage, cephalhematoma, conjunctival petechiae and excessive capillary fragility.

The authors suggest that the use of vitamins K and P during the latter months of pregnancy may prevent these hemorrhagic tendencies.

**HEMOPHILIA. PROBLEM OF SURGICAL INTERVENTION FOR ACCOMPANYING DISEASES. REVIEW OF THE LITERATURE AND REPORT OF A CASE.** C. G. Craddock, L. O. Fenninger and B. Simmons. From the University of Rochester School of Medicine and Dentistry and the Departments of Medicine and Surgery of Strong Memorial and the Rochester Municipal Hospital, Rochester, N. Y. *Ann Surg* 128: 888-903, 1948.

A case of hemophilia with the complication of acute appendicitis is presented. The patient received intensive antihemorrhagic therapy but despite a normal clotting time he continued to bleed profusely and expired four days postoperatively. A discussion of the significance of continued hemorrhage in the presence of a normal *in vitro* clotting time and its relation to the fundamental defect in hemophilia is presented. The authors conclude that the mere deficiency of the substance, antihemophilic globulin, cannot be the sole abnormality of coagulation in hemophilia. Emphasis is placed on the failure of the coagulation time to indicate the severity of the hemorrhagic tendency or the degree of response to treatment, the difficulty in choosing a suitable case for operation and the great difference in controlling interval hemorrhage as opposed to bleeding from an external site.

The authors reviewed the literature for instances of internal operative procedures in patients with hemophilia. Of four previously reported cases in whom the diagnosis of hemophilia was unequivocal two died from hemorrhage following operation while two recovered.

G. E. C.

**ACTION OF INTRAVENOUS INJECTIONS OF HISTAMINE ON THE BLOOD OF HEMOPHILIC CHILDREN.** H. N. Sanford, S. Butler and S. R. Kennedy, Jr. From the Presbyterian Hospital and the Department of Pediatrics, Rush Presbyterian Division of the University of Illinois, Chicago, Ill. *Am J Dis Child* 76: 609-615, 1948.

Following the observation of a slight decrease in blood coagulation time in adults with migraine treated with intravenous histamine, 6 hemophilic children were given histamine injections in increasing amounts (usually 0.3, 0.6, 0.8 and 1.0 mg.) on successive days during active cycles of bleeding. Determinations of the coagulation time were made on whole blood, plasma and platelet free (?) plasma obtained by centrifugation in waxed chilled tubes. A greater and more prolonged, although not permanent, decrease in coagulation time occurred in the hemophilic group with cessation of bleeding. The total number of platelets was not affected.

The authors conclude that this decrease in coagulation time is due to increased platelet disintegration (possibly of new and more normal platelets), their sole premise being that the defect in hemophilia is the result of abnormal qualitative platelet function. Although it has been shown that platelets are also essential for normal thromboplastic activity, the role of a plasma factor in hemophilia is not considered. This report is of interest, however, and further clinical trial and investigation with histamine in hemophiliacs appears warranted and may possibly reveal the mechanism of action which at present is not clear.

H. B. M.

**THE ROLE OF PLATELETS IN THE COAGULATION OF THE BLOOD.** A. J. Quick, J. N. Shanberg and M. Sefourni. From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wis. *Consilium* *Am J M Sc* 217: 198-205, 1949.

A technic was devised for varying the number of platelets without otherwise altering the plasma. The effect of the number of platelets was studied and the following observations made: (1) The greater the number of platelets, the sooner clot retraction begins and the smaller the final clot; (2) clot retraction

tion is characterized by a relatively long latent period followed by an accelerated phase and protracted completion (3) within a wide range in the number of platelets no significant change in coagulation time can be observed (4) as the number of platelets is diminished the speed of prothrombin consumption is decreased but within normal limits the final amount of prothrombin converted approximates a fixed value (5) below a critical number of platelets the consumption of prothrombin stops after a relatively short time This suggests that plasma contains an agent that inactivated the platelet enzyme, (6) in thrombocytopenic purpura of sufficient severity the consumption of prothrombin may be markedly diminished This suggests that in thrombocytopenic purpura a serious defect in coagulation is present which has heretofore been unrecognized because it is masked by a normal coagulation time

G E C

ÉTUDE DES MÉGAKARYOCYTES ET DES PLAQUETTES DANS DIVERS SYNDROMES HÉMORRAGIQUES (STUDY OF MEGAKARYOCYTES AND PLATELETS IN VARIOUS HEMORRHAGIC SYNDROMES) L. Revol and P. Morel  
Laboratoire de Pathologie Interne et Service du Pr. Croizat Lyon Sang 20 23-59 1949

The authors discuss the normal features of megakaryocytes in marrow smears They found in normal marrow more megakaryocytes than are usually stated to be present (up to 2,000 per million nucleated cells) but they agree about the percentage of the different cells from the megakaryoblast to the old cells They study platelet formation after splenectomy and find that platelets are essentially produced by the cytoplasm but sometimes a fragmentation of the nucleus is observed In 6 cases of idiopathic thrombopenias they found what Revol himself described in 1939 and what was confirmed by several authors, that is an increase of megakaryocytes (above 1,600 for 1 million of nucleated cells) but without increase of the young forms as it is commonly said

After splenectomy they found in 4 cases a striking platelet formation in megakaryocytes which was to be found as soon as one and a half hours after the operation with a maximum at the third day At the same time the number of megakaryocytes was reduced (from 5,900 to 3,900 in the average) In 2 cases however in spite of the same initial bone marrow splenectomy was not followed by the same platelet formation and the thrombocytopenia was not cured

In 2 cases of acquired thrombocytopenia the megakaryocytes were numerous in the marrow smears after splenectomy in the first case and transfusions in the second case a very slow platelet formation was observed In 3 cases of infectious thrombocytopenia the megakaryocytes were plentiful but there were numerous cytologic alterations

In 6 cases of hemorrhagic syndromes without thrombocytopenia they usually found an active bone marrow rich in megakaryocytes They discuss the effect of splenectomy and the advisability of this procedure

Twenty-seven good microphotographs illustrate this interesting study which ends with conclusions about the indications of splenectomy A very great number of megakaryocytes the lack of platelet formations seem to indicate the splenectomy

GAUCHER'S DISEASE WITH THROMBOCYTOPENIA AN INSTANCE OF SELECTIVE HYPERSPLENISM A CASE REPORT  
F. W. Davis, Abraham Genecin and Ernest W. Smith From the Medical Clinic The Johns Hopkins Hospital Bull. Johns Hopkins Hosp. 84 176-179 1949

The authors report an instance of thrombocytopenia unassociated with anemia or leukopenia in which hypersplenism secondary to Gaucher's disease was apparently the etiology Splenectomy resulted in correction of the thrombopenia and the hemorrhagic diathesis

W N V

THE INFLUENCE OF BRIEF PERIODS OF STRENUOUS EXERCISE ON THE BLOOD PLATELET COUNT E. B. Gribbin and A. T. Miller Jr From the Laboratory of Applied Physiology and Department of Physiology University of North Carolina School of Medicine Chapel Hill N. C. Science 109 64 1949

Reports in the literature on the effects of exercise on the platelet count are in conflict This work was performed in an attempt to solve whether exercise actually does change the platelet count Exercise consisted of running on a treadmill for five minutes at a speed of 7 miles an hour and a grade of 17.5 per cent or for two minutes at 12 miles an hour at zero grade Blood was obtained before exercise immediately after exercise and 10, 30, 60 and 90 minutes after exercise In spite of the fact that there was a

60-100 per cent increase in the leukocyte count, there was no increase in the platelet count. The authors suggest that the increased velocity of circulation may have destroyed the very labile platelets which may have covered up any increase in platelets

R C C

ROLE OF SPLENECTOMY IN THROMBOGENIC PURPURA *G Bagardus, J G Allen, L O Jackson and C L Spurr*  
From the Departments of Surgery and Medicine University of Chicago Chicago Ill Arch Surg  
58 16-27 1949

The authors present data on 20 cases of thrombogenic purpura 20 of which were treated medically and 10 treated by splenectomy Five recurrences were noted in the splenectomized group and 2 in the medically treated group Three of the patients with recurrence had the acute form of the disease and two the chronic The pathogenesis of the syndrome is discussed with emphasis on the importance of the capillary factor and the possible role of the entire reticuloendothelial system

The results are rendered somewhat difficult to evaluate by the fact that 14 of the patients were under the age of 22 years and 11 under 10 years of age and because 6 of the medically treated group and none of the surgically treated group had had symptoms for less than four weeks

W N V

THE EFFECT OF RUTIN IN THE CONTROL OF BLEEDING INTO THE RETINA *R W Hollenhorst and H P Wagner*  
From the Section on Ophthalmology Mayo Clinic, Rochester Minnesota Am J M. Sc 27 227-231, 1949

The clinical literature of the use of rutin in conditions of increased capillary fragility is discussed. The article serves as a useful review of the subject but the authors justifiably stress the variability of reports and their inability to draw any definite conclusions with the evidence at hand

C A F

EVALUATION OF THE VARIOUS CLINICAL SIGNS OF THROMBOPHLEBITIS AND EXPERIENCE IN THERAPY WITH ANTICOAGULANTS *D A Felder* From the Department of Surgery University of Minnesota, Minneapolis, Minn Surg Gynec & Obst 88 337-350 1949

The results of treatment of 91 cases representing 105 extremities with deep thrombophlebitis are reported together with a detailed discussion of the diagnostic signs methods of treatment type of venous thrombosis, and the primary disease process For practical purposes both the bland and inflammatory thromboses were called thrombophlebitis With the exception of eight patients who were treated with vein ligation anticoagulants (dicumarol and heparin) were used with an average of ten days of bed rest in, unless contraindicated mild Trendelenburg position

Although most of the patients had had one pulmonary embolism at the time of diagnosis of thrombophlebitis the results of anticoagulant therapy were considered satisfactory in that the incidence of secondary embolism was reduced from an expected 30 per cent to 2.17 per cent and that of secondary fatal embolism from an expected 25 per cent to zero An analysis of the primary condition indicated the importance of prophylactic postoperative anticoagulant therapy in patients with cancer and in those undergoing major gastrointestinal surgery hysterectomies and hip fixations

The controversy as to the relative merits of anticoagulant therapy vs vein ligation in the prevention and treatment of thromboembolism will probably remain unsettled for some time It would seem however that both have a place in the management of this disorder and that the indications for each should be determined more on the basis of the type of thrombophlebitis the underlying disease and condition of the patient availability of laboratory control and the estimated risk of fatal embolus It is quite possible that the incidence of death from pulmonary embolism is much lower than generally believed (see Surg Gynec & Obst 88 373 1949)

## TRANSFUSION

ON THE CHEMICAL STERILIZATION OF BLOOD AND BLOOD PLASMA *F W Hartman G H Mangen N Friley and E Jackson* From the Department of Laboratories Henry Ford Hospital, Detroit Michigan Proc. Soc. Exper Biol & Med 78 148-154 1949

In the hope that a means might be supplied for reducing the high incidence (4.5-7.2 per cent) of homologous serum jaundice or of eliminating this risk altogether in transfusion recipients and in view of the essential unavailability of effective irradiation techniques for the sterilization of blood and blood derivatives the authors have investigated the merits of nitrogen mustard (HN) as a sterilizing agent. Selection of this compound for study was based on the following considerations: its presumed effect on nucleoproteins; its ready susceptibility to spontaneous hydrolysis in buffered aqueous solution; forming relatively nontoxic end products; the parallelism of its activity with that of ionizing radiations; and its availability in purified form suitable for parenteral administration.

It was demonstrated that HN is capable of effective bactericidal and virucidal action in whole blood, blood plasma and blood serum without causing major alterations in the properties of either the plasma components or the red blood cells. Virucidal potency appeared to be greatly enhanced by decreasing the pH to 7.2 or below, possibly attributable to a reduction in the rate of HN decomposition or to a lessened reactivity with other competing substances and at these pH levels sterilization was considered to be accomplished with concentrations of the drug not exceeding 500 mg per liter. No evidence of antigenic or other toxic reactions was produced in two dogs and two humans receiving repeated injections of plasma so treated. Plasma complement, immune bodies, phosphatase and fibrinogen were apparently unaffected by exposure to sterilizing doses, but a marked reduction of prothrombin activity was observed. In vitro studies failed to demonstrate a significant increase in the rate of erythrocyte deterioration in stored blood following the application of virucidal dosages of HN. In vivo erythrocyte survival studies, however, have not as yet been completed.

## IRON THERAPY AND METABOLISM

PREPARATION AND STANDARDISATION OF SACCHARATED IRON OXIDE FOR INTRAVENOUS ADMINISTRATION

J. A. Nissem and J. M. Robson. From Guy's Hospital Medical School, University of London, London, England. *Lancet* 1: 686-689, 1949.

Details of methods of preparation and toxicity tests on various samples of saccharated oxide of iron are described. The toxicity varied considerably and seemed to be the result of gradual precipitation of free iron. This in turn it was thought might depend on the rate of metabolism of the sugar part of the molecule. Mice given lethal doses showed hemorrhagic lesions, probably due to multiple capillary emboli from iron precipitation. As a consequence of the difficulties encountered in producing uniform preparations the authors suggest that biologic standardization is essential.

S C

THE DERMAL EXCRETION UNDER CONTROLLED ENVIRONMENTAL CONDITIONS OF NITROGEN AND MINERALS

IN HUMAN SUBJECTS WITH PARTICULAR REFERENCE TO CALCIUM AND IRON. H. H. Mitchell and T. S. Hamilton. From the Division of Animal Nutrition, University of Illinois, Urbana, Ill. *J. Biol. Chem.* 178: 345-361, 1949.

In studies of 6 subjects exposed to humid heat, these authors found iron in amounts of 1 to 3 mg/liter of sweat. They estimated a daily loss of about 6.5 mg iron under minimal sweating conditions.

This magnitude of iron excretion is not in harmony with present concepts of iron metabolism. In fact, such a daily loss would appear to be more than the normal individual is able to absorb. Obviously further studies are necessary before these findings can be interpreted.

C A F

## PIGMENT METABOLISM

INFLUENCE OF FOLIC ACID ON PORPHYRIA. V. Avasniškova. From the 3rd Medical Clinic, Charles University, Prague. *Čes. lek. čas.* 8: 633, 1948.

A woman suffering from a cutaneous form of porphyria was eliminating 200 gamma uroporphyrin (and the same amount of coproporphyrin III) per liter of urine. Porphyria was accompanied by severe hypochromic anemia and raised level of plasma iron. Folic acid administered in the daily dose of 15 mg proved to be highly effective. Skin manifestations disappeared, pigmentations cleared up, general feeling improved and uroporphyrin disappeared entirely from the urine.

M. N

CLINICAL INVESTIGATIONS IN THE DIFFERENTIATION OF STERCOBILINE AND UROBILINE WITH THE PENTDYOPENT REACTION *W. Stieh* From I. Medizin. Klinik der Universität München (Germany) *Klin. Wochschr.* 365-367, 1948

Differentiation of stercobiline and urobiline is made possible by the pentdyopent reaction. Clinical examinations showed that the hitherto assumed urobilinuria is actually a stercobilinuria. Presence of urobiline IX<sub>a</sub> in urine is always sign of a pathologic process. Stercobilinuria and elimination of stercobiline in the feces is found in pernicious anemia, hemolytic jaundice, malaria and in parenchymatous icterus. Pure urobilinuria can be encountered in icterus of total biliary occlusion. Preponderant urobilinuria can be seen in beginning parenchymatous liver affection. Increase of stercobiline comes later. The choical differentiation of both substances opens new diagnostic possibilities.

C. M.

MECHANISM OF HYPERBILIRUBINEMIA IN THE NEWBORN INFANT. EXPERIMENTAL DEMONSTRATION OF FUNCTIONAL HEPATIC IMMATUREITY *G. J. Fasbina* From the Departments of Pathology and Pediatrics, Southwestern Medical College of the Southwestern Medical Foundation, Dallas, Texas. *Am. J. Dis. Child.* 76, 196-202, 1948

Twenty-one normal infants of approximately similar weight were studied during the neonatal period by means of daily red blood cell counts and hemoglobin determinations, red cell volumes and plasma bilirubin levels. In most of the infants, determinations were made of the bilirubin content in the meconium excreted during the first three days. The velocity constant of excretion of bilirubin was determined in 18 infants by the method of Weech et al. The relation of maternal and fetal isobemagglutinins to the development of neonatal hyperbilirubinemia was investigated in 50 other normal infants.

Evidence is presented which strongly suggests that physiologic hyperbilirubinemia is not purely if at all hemolytic in origin but due mainly to functional immaturity of the liver before and for a variable period after birth. The degree of hyperbilirubinemia could not be correlated with the magnitude of the fall in red cell count and packed red cell volume nor with mother-child ABO and Rh incompatibility. There was an inverse correlation between the amount of bile pigment in the first meconium and the height of the plasma bilirubin rise during the first week of life. Impairment of the bilirubin excretory capacity of the liver was demonstrated in infants with hyperbilirubinemia, whereas normal excretory function was found in infants whose plasma bilirubin levels had returned to normal.

SEPTEMBER, 1949

### MEDITERRANEAN HEMOPATHIC SYNDROMES

By V CHINI, M.D., AND C MALAGUZZI VALERI, M.D

FROM investigations made during the past ten years in our laboratory and on the basis of several recently published reports, we are now in a position to attempt a classification of Cooley's anemia and allied conditions. We have used the term Mediterranean hemopathic syndromes for a group of blood conditions which have a high incidence among the populations of some Mediterranean countries, and which have in common certain hematologic abnormalities, which represent different varieties of one great group of constitutional and hereditary blood diseases.

To this group belong, among others, two clinically well-defined and easily diagnosed forms, that is, Cooley's anemia, or Mediterranean anemia, and a hemolytic syndrome which about twenty years ago was popularized by Italian authors as hemolytic jaundice with decreased red cell fragility.

Cooley's anemia being universally known, it is superfluous to mention here its clinical features and blood picture. It was first described as a clinical entity by Cooley and collaborators,<sup>67 68 69 72 73 76</sup> and several American<sup>19 271 272 275</sup> and European<sup>62 63 169 199 251 262</sup> authors have widely contributed to its study. On the continent it has been the object of investigations particularly by Caminopetros<sup>22 34 35</sup> and various Italian workers (Cassano<sup>42</sup>, Ravenna and Cannella<sup>211</sup>, Ortolan<sup>182 183 184</sup>, Ortolan and Castagnari<sup>186</sup>, as well as by many others<sup>27 38 46 27 66 77 105 112 129 147 188 191 192 205 206 207</sup>).

The so-called hemolytic jaundice with decreased red cell fragility was first described in Italy by Rietti<sup>212 213</sup> and by Greppi<sup>133 134 135</sup> (1925-1928). Numerous cases have been published subsequently by Italian authors and more recently by others<sup>21 44 61 79 93 94 106 108 109 115 118 141 142 161 164 165 168 190 197 206 211 260 256 266 268 261a 261b 122 167 217 229 270</sup>. It is a familial hemolytic jaundice with a constitutional and hereditary element. Its fundamental feature, and the one which differentiates it from Minkowski-Chauffard's hemolytic anemia (acholuric jaundice), is the presence of an increased instance of the red cells to hypotonic solutions. Other less constant features are hypochromic microcytosis and in nearly all cases ovalocytosis and poikilocytosis.<sup>149 165 197</sup>

From the Clinica Medica University of Bari Bari Italy

Clinically, its differential characteristics are a less intense degree of anemia, less intense and less frequent hemolytic crises, and less favorable results from splenectomy<sup>84 175 135 14\* 166 49</sup>

The clinical and hematologic features of the condition just described have led us to put it in the same general category with Cooley's anemia. Several investigators,<sup>106 10 118</sup> especially American authors (Wintrobe et al.<sup>4</sup>, Atkinson<sup>11</sup>, Dameshek,<sup>81</sup> and others), have interpreted such cases as mild or asymptomatic forms of Cooley's anemia<sup>275 277</sup> and the prevalent opinion now is that there exists one disease entity—that is, Cooley's anemia—which may appear under at least two fundamental forms, that is, (a) *severe* form, the classic Cooley's disease, which develops nearly exclusively in children, has a rapidly fatal course,<sup>\*</sup> and is characterized by an intense degree of anemia, splenomegaly with erythropoietic metaplasia of the spleen, and by typical bone changes, and (b) a *mild* form (hemolytic jaundice with decreased red cell fragility of Italian authors), whose course is less rapid, allowing patients to reach adult age. With this latter form should be grouped a good number of cases which have been described as

Cooley's syndrome or Mediterranean anemia of adults<sup>1 5 9 17 5 49 53 5 80 91 95 100 104 150 15\* 178 187 2 6 75\* 253 766</sup>

Observations in a large series of cases, investigations of the familial element and on the modes of transmission of the fundamental characters of the two conditions, analysis of well-defined clinical and hematologic pictures have allowed us to develop a broader aspect of this group of conditions and a more satisfactory classification of the various forms.

These investigations, which began with the work of Caminopetros<sup>23 24 25</sup> and others,<sup>22</sup> have been further developed by several Italian (Angelini<sup>3</sup>, Micheli and collaborators<sup>155 166</sup>, Pontoni,<sup>207</sup> Gatto<sup>173 124 178</sup>, Chini<sup>51 54 57 179</sup>, Silvestroni and Bianco<sup>277-243</sup>) and American workers (Dameshek,<sup>61 3</sup>, Valentine and Neel<sup>176 177 262</sup>, Smith<sup>74 248</sup>, McIntosh and Wood<sup>16</sup>, Cooley<sup>70</sup>)

By proposing the term Mediterranean hemopathic syndromes we do not intend to suggest that such conditions affect exclusively Mediterranean ethnic groups. Cases have been published recently from other parts of the globe whose clinical and hematologic pictures may be included in this group of diseases.<sup>21 41 82 86 96 97 110 120 132 136 140 219 223 254 760</sup> However, they represent isolated cases, the diagnosis of some of which might be worth reconsidering.

On the other hand, there seems to be little doubt that the conditions under discussion have a particularly high incidence among some populations in the Mediterranean area (Greece, Mediterranean islands, southern Italy, Italian district of Ferrara) and among some ethnically related populations.†

(x) Among the members of families with cases of Cooley's anemia the presence

\* Therapeutic attempts have been made with splenectomy<sup>47a, 52 125 130 139 148 205 248 251</sup>

† Further statistical study may reveal the existence of blood diseases belonging to this group in other countries. In any case it is justified to state that their incidence is by far higher among the inhabitants of some Mediterranean regions. Therefore the suggested term Mediterranean hemopathic syndromes seems to us appropriate and has been adopted for the sake of simplicity.

can invariably be found of subjects (parents, brothers and other siblings) who exhibit some hematologic changes, the most frequent and characteristic being an *increased red cell resistance to hypotonic solutions*. This feature, which was first pointed out by Caminopetros<sup>22 24 25</sup> and by Angelini,<sup>8</sup> has been confirmed by numerous other observations and is now a generally accepted characteristic.

Together with the decreased red cell fragility, other blood changes are found, the most common being hypochromia, microcytosis and leptocytosis. Hypochromic microcytosis with decreased red cell fragility is the fundamental hematologic picture found in siblings of cases of Cooley's anemia (Caminopetros, Angelini, Micheli and collaborators, Gatto, Chini, Silvestroni and Bianco, Smith, Valentine and Neel, Dameshek, and others).

(2) This blood picture, which is also found in siblings of cases of hemolytic jaundice with decreased red cell fragility (Rietti, Greppi, and others), has been termed by Chini as *Mediterranean hematologic disorder*.<sup>55</sup> Valentine and Neel called it mild form of Cooley's anemia or thalassemia minor (thalassemia minima, according to Gatto<sup>127 128</sup>). Silvestroni and Bianco, who found these changes in a number of cases from numerous observations among Italians from the South,<sup>22 227 229 230 231</sup> called it microcytemia.<sup>233 236 237 241 247</sup> However, as it is pointed out by Dameshek and by Smith, a microcytic anemia is in these cases often accompanied by the presence of large, pale, thin macrocytes, whose hemoglobin content is unevenly distributed within the cell (target cells or leptocytes) and which are to be considered as characteristic elements.<sup>248</sup>

(3) Therefore, the Mediterranean hematologic disorder with the same fundamental blood change (decreased red cell fragility) is present in siblings of cases of Cooley's anemia and hemolytic jaundice with decreased red cell fragility.

From the point of view of the nosologic affinity of the two main forms<sup>51 54 228 236 238 239</sup> one can hardly overlook the importance of this common element, and we think it justified to assume that both forms affect subjects who are carriers of the mentioned hematologic taint. This point has been stressed by Gatto,<sup>123 124 128</sup> Chini<sup>51 54</sup> and, as the result of a great number of observations, by Silvestroni and Bianco.<sup>228 236 238 239 241 242</sup>

(4) *Carriers of the Mediterranean hematologic disorder are found in those regions and among the populations where Cooley's anemia is incident* (it is probable that many cases go undiagnosed). The disorder represents a necessary early stage for the appearance of Cooley's anemia.

Subjects who are carriers of the disorder may appear to be *quite healthy*, and have no complaints. The disorder is usually detected if it is looked for among families with cases of Cooley's anemia and of hemolytic jaundice with decreased red cell fragility or accidentally as the result of routine investigations. It is apparently transmitted as a dominant characteristic (Gatto<sup>123 124</sup>, Dameshek<sup>82</sup>, Smith<sup>47 248</sup>, Silvestroni and Bianco<sup>40</sup>), and its presence has been followed up in three to four generations of the same family tree.

(5) In many cases the disorder is accompanied by an anemic state. The anemia of these cases cannot be ascribed to any appreciable cause, it is benefited but slightly

by the usual antianemic remedies (liver extracts, iron, blood transfusions), it may last for years or decades, slight splenomegaly may be present. These cases may exhibit very different pictures.

The prevalence in some cases of one or the other morphologic changes may in time permit the nosologic isolation of well-defined syndromes and the use of an appropriate terminology (for instance, the target cell syndrome of Dameshek<sup>11</sup>, the target-oval cell syndrome of the same author, ovalo-poikilocytic hypo-

markedly hypochromic, less frequently hyperchromic (Patrassi and Taglioni<sup>197</sup>, Chini<sup>55</sup>, Muratore<sup>174</sup>) In the hypochromic cases there is nearly always microcytosis, with hyperchromia, macrocytosis may also be found In nearly all cases marked ovalocytosis is observed, in many cases aniso-poikilocytosis is prevalent, and in some we find schistocytosis similar to that found in Cooley's anemia<sup>74 155 166 182</sup>, that is to say, morphologically one finds a blood picture very much resembling Cooley's anemia, with the exception of circulating erythroblastosis

We can, therefore, refer to these various pictures as *varieties of the anemic form of the Mediterranean hematologic disorder* Some of these varieties are poorly defined, others resemble very nearly Cooley's anemia

The clinically well-defined varieties of this anemic form are usually hypochromic, microcytic, ovalocytic, aniso-poikilocytic and schistocytic Besides, in many cases,<sup>173 247 248 261a 261b 274</sup> stippled cells and target cells (Dameshek) are present but the latter do not appear to be characteristic of these forms<sup>18 24 87 88 137 202 220</sup> There is marked hyperplasia and erythroblastic anaplasia of the bone marrow<sup>27 84 122 143 183</sup>

In spite of discordant views,<sup>118 221</sup> a distinction has to be made here between this type of anemia—even its hypochromic microcytic variety—and achylic hypochromic anemia (idiopathic hypochromic anemia), differentiating points being its ethnographic distribution, the high iron content of the blood (Chini, and Perosa<sup>60</sup>, Perosa<sup>201</sup>), the nearly absent response to iron therapy, the usual presence of normal gastric secretion,<sup>64</sup> the absence of some clinical signs which are usually found in idiopathic hypochromic anemia, such as glossitis, dystrophic changes of the fingernails, Plummer-Vinson syndrome<sup>64</sup>

(6) In numerous cases of Mediterranean hemopathic syndrome we find a *marked hemolytic element* These cases are more readily recognizable clinically and have been termed hemolytic jaundice with decreased red cell fragility (Rietti<sup>212 213 215 216</sup>, Greppi<sup>133 134 136</sup>) The picture is that of the Mediterranean hematologic disorder with anemia of one or the other variety (increased resistance to hypotonic solutions, occasional ovalocytosis,<sup>214</sup> presence of target cells oval-target cell syndrome of Dameshek<sup>82</sup>) There is marked hyperplasia and erythroblastic anaplasia of the bone marrow, but no erythroblasts are found in the circulating blood and hemolysis is increased In some cases the hemolytic index reaches values as high as in acholuric jaundice<sup>55 172</sup>

Jaundice is present, there is marked splenomegaly and intense hemolytic crises may occur The hemolytic disturbance may respond effectively to splenectomy<sup>62 172</sup> Histologically, the spleen shows changes of the hemolytic type with no erythropoietic metaplasia, which is a differentiating point from Cooley's anemia The main feature in these cases is the increased hemolysis, a point which should not be overlooked in diagnosis and treatment (splenectomy)<sup>2 3 135 142 166</sup> Operation is followed by a reduced hemolysis, but there is no effect on the morphologic changes, which in some cases are even more accentuated after splenectomy<sup>5\* 53</sup> In fact, some cases after splenectomy show a marked and persistent erythroblastemia<sup>2 3 75 74</sup> The postoperative picture resembles more closely that of Cooley's

\* Metrorrhagia

anemia chiefly on account of the erythroblastemia and in some cases because of bone lesions as seen in the x-ray films <sup>2 3 53 202</sup>

(7) Besides these varieties of the Mediterranean hematologic disorder with jaundice and hyperhemolysis, cases are seen in which jaundice is evident but no increased hemolysis is found. The hemolytic index of these patients is normal or even lower than in normal cases, in spite of the obvious presence of jaundice and of the high values of bilirubin in the blood by the indirect test. In the absence of increased hemolysis we cannot term them as cases of hemolytic jaundice. These cases have some points in common with the so-called *juvenile intermittent jaundice of Meulengracht or nonhemolytic prehepatic jaundice*<sup>84 92 181 194 195 196</sup> and they represent a fairly large number of cases of Mediterranean hemopathic syndromes (Patrassi and Taglioni<sup>197</sup>, Cassano and Benedetti<sup>45</sup>, Chini<sup>54</sup>, Malaguzzi-Valeri<sup>149</sup>, Castaldi and Leonardi<sup>121</sup>)

It has been suggested by various authors<sup>45 54 197 208</sup> and recently confirmed by the work of Perosa on hemoglobin tolerance curves, that in subjects affected with this type of jaundice, there is a derangement of the liver function in the sense that the transformation of bilirubin from the indirect to the direct form and its subsequent elimination from the blood do not take place.

A hepatic factor of this type may be present even in the full fledged case of hemolytic jaundice with decreased red cell fragility, in which a more or less marked hyperhemolysis is found. In fact, in these cases one often finds a discrepancy between the hemolytic index and the values of the indirect bilirubin of the blood, and also a delayed direct Van den Bergh reaction<sup>84 79 116 197 201</sup>. These findings have been interpreted in various ways, for instance, they have been ascribed to liver dysfunction, to the presence of an abnormal pigment not detected by Nencki's reagent, etc. (investigations on this subject are being carried out in our Institute)

(8) All these different forms have some common fundamental elements which permit us to consider them as belonging to one great group. These elements are (a) Their nearly exclusive limitation to Mediterranean people, (b) The presence of a constitutional, familial and hereditary element, (c) The increased resistance of the red cells to hypotonic solutions.

Therefore, we find it justified to collect them in one group under the term of Mediterranean hemopathic syndromes, and to consider the Mediterranean hematologic disorder as their fundamental pathogenetic factor.

The pathogenesis of the single clinical pictures is still very obscure.

On the basis of our present knowledge, mainly from the analysis of the familial tendency of these syndromes, it seems to us that something can be said on the pathogenetic connections between the so-called Mediterranean hematologic disorder and Cooley's anemia and on the etiopathogenesis of the so-called hemolytic jaundice with decreased red cell fragility.

With regard to Cooley's anemia, one important point has been brought to evidence from the study of the parents of the patients, and that is that where the investigation has been adequate, *both parents* of an individual affected with Cooley's

\* Splene-tomy

anemia have been found to be carriers of the Mediterranean hematologic disorder

It was Caminopetros<sup>34 35</sup> who first called attention to this point, even if he did not stress it as a fundamental feature in the familial tendency of the disease, and it was confirmed by Angelini<sup>8</sup> and later by Micheli, Penati, Momigliano-Levi<sup>115</sup> and others (Panoff<sup>189</sup>)

In 1939, Chini,<sup>51 52</sup> on the basis of the reports from Caminopetros, Angelini and Micheli, stressed the unusual fact of the presence of a hematologic taint in both parents of patients suffering from Cooley's anemia and stated that the findings could not be ascribed to mere coincidence.<sup>51 57</sup>

Subsequently (1941), further reports from other authors (Ortolani and Vallisneri<sup>187 262</sup>, Wintrobe and collaborators<sup>274</sup>, Atkinson<sup>14</sup>, Pehu and Leriche<sup>199</sup>) led Chini<sup>51</sup> to state that this bilateral hereditary tendency was to be considered as a fundamental factor in the pathogenesis of Cooley's anemia

Independently, in 1941-1942, Gatto<sup>123 124</sup> made his first report on the results of his investigations on the members of the families of 8 cases of Cooley's anemia. His conclusions were that increased resistance of the red cells to hypotonic solutions and microcytosis, as a rule hypochromic and accompanied by ovalocytosis and poikilocytosis, were constantly present in both parents of patients with Cooley's anemia. According to Gatto, this trait (hyperresistant microcytosis)

is a dominant hereditary characteristic which is carried as a heterozygous gene and Cooley's anemia develops only in subjects whose parents are both affected with the disorder and who carry the hematologic characteristic as a homozygous gene. The bilateral hereditary element in these cases has been subsequently confirmed by various authors (Pierce<sup>204</sup>, Valentine and Neel<sup>178 177 262</sup>, Dameshek<sup>82</sup>, Smith<sup>247 248</sup>, McIntosh and Wood<sup>162</sup>, Trincao<sup>260</sup>, etc.<sup>18</sup> and recently in Italy by Burgio<sup>97</sup>, Careddu and Magrassi<sup>41</sup>, Silvestroni and Bianco) in a large number of cases.<sup>338 341</sup>

In Gatto's opinion, Cooley's anemia is an example of *dominant hereditary characteristic with lethal homozygous effect*

In the present state of our knowledge this seems to be the fundamental fact which has been agreed upon from the study of the familial tendency of Cooley's anemia and allied syndromes

It would therefore appear that Cooley's anemia represents the most severe of the Mediterranean hemopathic syndromes. Its severity seems to be caused by the lethal homozygous effect of the presence of the trait in both parents.\*

\* As Chini pointed out in 1941, if it is true that typical Cooley's anemia only affects those subjects whose parents are both carriers of the Mediterranean hematologic disorder, then we should not use the term of mild forms of Cooley's anemia to indicate the various forms of Mediterranean hemopathic syndromes or the cases of apparently healthy carriers of the Mediterranean hematologic disorder. In cases of Mediterranean hemopathic syndromes only one of the parents is a carrier. In a typical case of Cooley's anemia we never see a gradual attenuation of the symptomatology, so as to make it possible to identify the case with one or the other variety of the Mediterranean hemopathic syndromes, and we never see a case of Mediterranean hemopathic syndrome becoming so severe as to resemble a typical case of Cooley's anemia. One could use the term of mild forms in these cases as suggested by some American authors, if there existed a transition in some of them from the mild to the severe form. This

Of this trait we know only some features which are more readily detectable, the decreased red cell fragility and often the hypochromic microcytosis, also, according to Dameshek,<sup>61</sup> the target cells or leptocytes and, according to Smith,<sup>248</sup> the thin and pale macrocytes and the stippled cells. These physical and morphologic changes reveal the presence of a more profound structural disorder of the red cell whose essence is still obscure (Pontoni<sup>208</sup>, Chini<sup>64</sup>, Rietti<sup>216</sup>). Other characteristics of the trait (first described by Caminopetros<sup>24 36</sup> and in Italy by Gatto,<sup>123 124 126</sup> followed by Chini,<sup>61 64</sup> Silvestroni and Gentili<sup>242</sup>) are in the somatic line. The presence of the Mediterranean hematologic disorder is frequently found in subjects with high and thick zygoma cheek bones (*facies microcytica*, according to Silvestroni and Gentili<sup>242</sup>). What we have often found is an increased distance between the zygomas. However, it should be noted that this characteristic is frequently found among the population of Southern Italy<sup>64 68</sup> and that on the other hand subjects who exhibit a mongoloid face may not be carriers of the Mediterranean hematologic disorder, though they may be affected with some other blood disturbance.

With regard to hemolytic jaundice with decreased red cell fragility, here also some family members of the patients are carriers of the Mediterranean hematologic disorder, though only one parent is affected and not both as in Cooley's anemia.

In some family members of cases affected with this condition, a constitutional hyperhemolytic state is also found, either in the same family side of the carrier or in the opposite.<sup>171</sup>

This characteristic is in some cases quite evident,<sup>44 171</sup> in others only slightly pronounced (slight increase of the red cell fragility, and at the same time an in-

view finds confirmation in the clinical analysis of Cooley's anemia and of those Mediterranean hemopathic syndromes whose characteristics are well-defined. In a sense the terminology suggested by Valentine and Neel<sup>262</sup> of thalassemia major (Cooley's anemia) and thalassemia minor seems to us more appropriate though thalassemia minor would seem to include well-defined syndromes some of which are of marked severity and for which the term minor could hardly seem acceptable. It should be noted that for the carrier state Gatto uses the term thalassemia minima.<sup>127 128</sup> While the view expressed in this paper has on one hand more consideration of the genetic factors whose etiopathogenic nature has been established on the other hand it does not disregard the importance of the clinical characteristics: our scheme of classification is very similar to that of Dameshek.<sup>42</sup> Cooley's anemia represents the extremely severe and the fatal among the Mediterranean hemopathic syndromes. It is a constitutional familial and hereditary condition but it is not transmissible because its appearance (lethal homozygous effect) makes procreation impossible. At least this is what we know from nearly all cases that have been described (infantile prepubertal mortality). With regard to this point a re-examination of all the published cases of Cooley's anemia in adults would seem necessary in order to make a detailed assessment of their genetic elements and to find out whether there did or did not exist bilateral hereditary factors. For the cases of Cooley's anemia in adults which have been published (two personal cases included) Chini has suggested the term of syndromes of the Cooley type.<sup>49 52</sup> It is a subject still open to investigation. The term mild forms of Cooley's anemia could be used for the brothers of a typical case of Cooley's anemia whose parents are both carriers of the Mediterranean hematologic disorder and who exhibit clinical hematologic x-ray and histologic pictures (erythrocytic metaplasia outside the bone marrow) which very nearly resemble even in their degree of severity typical Cooley's anemia. Such cases as these have been published.<sup>14 15 25 150</sup>

crease of the maximal resistance, spherocytosis) Some authors have suggested the term of mixed forms of hemolytic jaundice, and in a wide sense, of hemolytic diathesis, common to both forms<sup>44 266 267</sup> However, the observations with regard to this group of cases are still isolated and it is not possible at present to come to any conclusions

It is quite possible that the presence of a constitutional hemolytic factor may be of importance in the pathogenesis of some Mediterranean hemopathic syndromes which show a marked hemolytic element This should be more common in those regions where the Mediterranean hematologic disorder and hyperhemolysis are comparatively frequent events And such is the case in some districts of Southern Italy, the origin of the majority of the presently published cases of "hemolytic jaundice with decreased red cell fragility

This, however, is not the only factor which may be responsible for the hemolytic element of the condition, the structural changes in the red cells may play their role (microschistocytosis<sup>155 156 157</sup>) or the cause may lie in a combination of various morbid factors, as well as in splenopathic conditions, in a wide sense In this respect, we can hardly overlook the importance of malaria, whose role has also been discussed with regard to Cooley's anemia<sup>70 26 39 50 51 58 90 128 151 160 191 225</sup>

A hemolyzing action of blood plasma has been found by Frontali and Rasi<sup>117</sup>, however, this has not been confirmed by Chini and collaborators, who could detect it only in cases in which the blood cholesterol values were very low<sup>20 58 102</sup>

The question is still very obscure We still do not know why and how carriers of the hematologic characteristics of acholuric jaundice at a certain time become affected with hyperhemolysis In some cases we find an intercurrent illness, in others the real cause cannot be found, the hemolytic character of the condition being then termed idiopathic

Very little has been known regarding factors which determine or help in the transition from the simple stage of hematologic disorder to that of anemia in its different varieties (ovalo-poikilocytosis, etc.) Occasional factors, such as infectious diseases, hemorrhages, abundant menstruations, food deficiencies, endocrine disturbances, etc., may contribute, but constitutional and hereditary elements of various type may intervene, and this side of the question is now being widely investigated (significance of ovalocytosis, presence in some family groups of some other hemopathic condition, possible influence of malaria on carriers of the trait)<sup>54 55 222 234</sup>

With regard to the fundamental structural derangement of the red cells which is the cause of their abnormal physical sedimentation rate,<sup>154 158</sup> etc., and morphologic state, the question is still obscure

As has been said before, there probably exists a profound biochemical alteration of the red cells which is most intense in Cooley's anemia, but may be present in a lesser degree in the other Mediterranean hemopathic syndromes

As suggested by Whipple and Bradford<sup>271 272</sup> for Cooley's anemia, in the other syndromes of the group there is also possible the presence of an abnormal capacity

for utilizing iron and elaborating hemoglobin. This hypothesis is supported by the presence of erythroblasts with a red fluorescence in the bone marrow (Freudenberg and Esser<sup>113, 114</sup>) and by other abnormalities in the metabolism of porphyrin (Lichtwitz<sup>148</sup>, Vannotti<sup>254</sup>, Tropp and Penef<sup>261</sup>), by the high values of blood iron in spite of the constant and in some cases quite marked hypochromia (Perosa<sup>201</sup>, Chini and Perosa<sup>60</sup>, Amato<sup>6</sup>, Cartwright<sup>42</sup>), and by the variations in the resistance of hemoglobin to alkaline denaturation in Cooley's anemia (Vecchio<sup>255</sup>, Bianco<sup>22</sup>, Putignano and Fiore-Donati<sup>209</sup>). It appears, however, that there is no change in the crystallographic and spectrophotometric characteristics of hemoglobin (Marmont and Bianchi<sup>159, 160</sup>).

In spite of the methodical work of Bussi<sup>29</sup> and of Astdal and collaborators,<sup>10, 11, 12, 13</sup> on erythroblastometric curves and on bone marrow maturation, there is no conclusive evidence of the significance of microcytosis and on the question of its interpretation as a congenital abnormality.

Lehndorff,<sup>145</sup> Caminopetros<sup>25</sup> and others (Chini<sup>51</sup>, Gatto<sup>123, 124, 128</sup>, Fanconi<sup>89</sup>, Heilmeyer<sup>128</sup>, etc.) favor the hypothesis that the hematologic abnormality which is fundamental in Cooley's anemia, that is the Mediterranean hematological disorder, is due to a process of mutation in some groups of Mediterranean populations.

That a process of mutation may have particularly affected some Mediterranean groups which are still recognizable from their facial configuration (width and thickness of the zygoma, cheek bones) was pointed out by Gatto in 1942 and recently confirmed by the results of investigations carried out by Graziosi,<sup>131</sup> on fossilized skulls from the superior paleolithic ages found in Sicily.

The high incidence of the Mediterranean hematologic disorder in some regions (investigations carried out among Americans of Italian descent by Valentine and Neel<sup>176, 177</sup>, in Italy by Silvestroni and Bianco<sup>229, 230, 241</sup>, Careddu,<sup>40</sup> Careddu and Magrassi<sup>41</sup>, Leonardi and collaborators<sup>145</sup>, Bianco<sup>22</sup>, our own investigations still under way, by Banton<sup>15</sup> in Cyprus), and the etiopathogenetic connections of the disturbance with the various Mediterranean hemopathic syndromes, including Cooley's anemia, represent a subject of great social importance. The widespread diffusion and the intensity of the morbid characteristics which are transmitted to their descendants by the carriers of the trait had been stressed by Chini<sup>57</sup> in 1939 and particularly emphasized by Caminopetros (1937, 1938). Such diffusion is now being more widely revealed through large scale investigations on the incidence of the Mediterranean hematologic disorder among the population of some districts of Italy.

Caminopetros<sup>25</sup> had suggested the necessity of advising the carriers of the trait against marriage. The recently established evidence that Cooley's anemia only appears in individuals whose parents are both carriers of the Mediterranean hematologic disorder is of great importance in this respect, and especially if it receives further confirmation, will allow for a less extreme view with regard to marriage limitations. In fact, as suggested by Silvestroni and Bianco,<sup>241</sup> and as we

have been advising for some time to the family members of our own cases, it would be sufficient to discourage marriage between persons who are both carriers of the disorder

Paleontologic investigations have revealed the presence of particular skeletal lesions, especially of the skull, in the skeletons of individuals belonging to races now nearly completely extinct

The analysis of skulls found in ancient cemeteries or belonging to mummies still in a state of very good preservation, of skeletons from ancient native populations of America, Incas from Peru (Williams<sup>79</sup>), Indians from Colombia (Feingold and Case<sup>101</sup>), Aztecs from Mexico, Maya Indians from Yucatan (Moore<sup>170</sup>) (it should be noted that the Indians from the northern parts of South America and those from Mexico appear to have a common origin) in some necropolises from Arkansas (Wakefield and collaborators,<sup>68</sup> etc.), has shown the existence of the same typical and unmistakable skeletal lesions which we now find in individuals suffering from sickle cell anemia, Cooley's anemia, or, to a lesser extent, in cases of Mediterranean hemopathic syndromes (Perosa and Viterbo, etc.) Not without foundation do students of paleontology believe that the extinction of those ancient populations was contributed to by the high incidence among them of some blood diseases which probably developed through processes of human mutation on a widely hereditary and familial basis (Williams and Moore) The recent report of cases of sickle cell anemia among some native populations of Mexico, whose anthropologic characteristics are very similar to those of ancient Aztecs (Wallace and Killingsworth<sup>69</sup>) has led some authors to believe that those remnants of a disappearing race have inherited from their ancestors some genetic characteristic.

We still do not know whether such bone lesions are to be ascribed to blood diseases similar to sickle cell anemia or to Cooley's anemia or to some other hemopathic condition with a more or less accentuated hemolytic character (bone lesions, which radiologically resemble those found in Cooley's anemia are also seen, and in some cases quite marked, in acholuric jaundice and in other forms of hemolytic anemia [Gänsslen<sup>119</sup>, Caffey<sup>12</sup>, Perosa and Viterbo, etc.<sup>61 76 85 218 211</sup>]), or even to nonhemopathic conditions The study of the paleolithic skulls found in the caves of St. Teodoro, Sicily, has revealed the presence in them of diffuse osteoporosis (Gatto, Graziosi) Osteoporosis of this type has been observed by Adachi<sup>4</sup> in prehistoric skulls in Egypt Owing to war restrictions and to lack of proper equipment, we have been unable to carry out a group of investigations which we had planned here in Puglia (necropolis of Canne) We are not aware that other investigations of this kind have been carried out elsewhere, except those of Caponnetto<sup>13</sup> on 25 skulls belonging to the Anatomical Museum of Catania, Sicily In 13 of them the author found osteoporosis, in some cases a moderate degree of radial striation of the skull

It can be assumed with some foundation that the diseases—probably blood conditions—which had been the cause of the characteristic lesion of the skeleton, contributed to the gradual extinction of those ancient races

Paleontology thus throws light on the history of disappeared populations offer

ing new possibilities of interpretation. It can lend justification to the warning of Caminopetros, because there is no doubt that the spreading of the Mediterranean hematologic disorder with its dominant character will inevitably lead, through an increase in the number of marriages between carriers of the disturbance, to the appearance of an always increasing number of cases of Mediterranean hemopathic syndromes and of fatal cases of Cooley's anemia.

The study of the Mediterranean hemopathic syndromes represents a great chapter open to research which involves difficult problems of clinical, historical and social importance.

# THE USE OF EXCHANGE TRANSFUSION FOR THE TREATMENT OF SEVERE ERYTHROBLASTOSIS DUE TO A-B SENSITIZATION, WITH OBSERVATIONS ON THE PATHOGENESIS OF THE DISEASE

By A S WIENER, M D , I B WEXLER, M D , AND J G HURST, A.B

IN PREVIOUS papers,<sup>1-3</sup> a method of treating erythroblastotic infants by exchange transfusion was described. In the cases reported, the disease had been produced by sensitization to the Rh<sub>0</sub> factor. Despite the publication of several well documented reports,<sup>4-15</sup> it is still not universally appreciated that typical erythroblastosis can also, though rarely, result from sensitization to the A and B factors. The purpose of this paper is to describe two unusual cases of severe erythroblastosis caused by sensitization to the A and B agglutinogens, respectively, which were treated successfully by exchange transfusion. In addition, observations will be described which are of significance with regard to the pathogenesis of such cases.

## MATERIALS AND METHODS

The most essential test in making an antenatal diagnosis of erythroblastosis is the titration of the antibodies in the maternal serum not only in cases caused by Rh sensitization but also in those produced by A-B sensitization. However, we have found that the methods which are optimal for titrating alpha and beta antibodies are not the same as those which have proved best in our hands for titrating Rh antibodies. This seems to be due in part to peculiarities of the agglutinogens and in part to peculiarities of the antibodies.

With regard to the agglutinogens or haptens these are presumably spaced at regular intervals about the periphery of the red cell and the following evidence is available to indicate that the A and B haptens are far more numerous than the Rh haptens.<sup>16-17</sup> (1) Red cells and stomata give much higher titers in inhibition tests with anti A or anti B sera than with anti Rh sera.<sup>17</sup> (2) Agglutinogens A and B are more potent antigens than Rh; however, this may also be explained on the basis of priming.<sup>18</sup> (3) Although properly performed Rh tests yield just as distinct reactions as ordinary A B tests, the clumps are much more fragile in the Rh tests indicating a smaller number of combining points. (4) While alpha and beta antibodies frequently produce complete lysis of sensitive cells in vitro as well as in vivo in vitro hemolysis is rarely seen in the Rh tests and then only in minimal amounts.<sup>19</sup> This again is presumably due to the smaller number of combining points on the red cell envelope. (5) The ability of strong univalent Rh antibodies to block Rh positive cells in contrast to univalent alpha and beta antibodies can be ascribed to the smaller number of specific Rh points to be coated.<sup>16</sup> These differences between the Rh and A B antigens could be expected to influence the optimal methods for their demonstration.

With regard to the nature of the antibodies the alpha and beta antibodies occur naturally while the Rh antibodies are practically always the result of active sensitization. The Rh antibodies are of two major types: agglutinins (bivalent antibodies) and blocking antibodies or glottinins (univalent antibodies). Univalent antibodies are relatively heat stable and traverse the placental barrier readily while bivalent antibodies are more heat labile and appear to be held by the intact placenta.<sup>9, 13, 18, 20, 21</sup> Thus as has been pointed out previously<sup>20-22</sup> it is the univalent antibody and not the bivalent antibody which crosses the placenta and produces fetal erythroblastosis. For demonstrating univalent Rh antibodies the block

From the Blood Transfusion Division and the Department of Pediatrics of the Jewish Hospital of Brooklyn, N. Y., and the Serological Laboratory of the Office of the Chief Medical Examiner of New York City.

Read before Society for the Study of the Blood, New York, February 17, 1949.

ing test<sup>22</sup> is the least sensitive method the plasma-conglutination test<sup>14</sup> is about five to twenty times as sensitive as the blocking test the albumin plasma test<sup>23</sup> is about two to four times as sensitive as the plasma-conglutination test while the acacia-conglutination test described below is about half as sensitive as the albumin plasma test \*

In the case of the alpha and beta antibodies the demonstration of specific glutinins (univalent antibodies) is considerably hampered by the practically universal presence of iso-agglutinins in human serum. Of course if the titers by the conglutination method are substantially higher than by the agglutination method the presence of the univalent antibodies may be inferred. However, in most cases the presence of univalent antibodies can be demonstrated † only by indirect means such as by their ability to traverse the placental barrier.<sup>12</sup> For demonstrating univalent alpha or beta antibodies the blocking test cannot be used at all. We do use the plasma-conglutination method but do not use the albumin plasma method because this gives no more sensitive results than the plasma method. The most satisfactory results for univalent alpha and beta antibodies were obtained by us with the acacia method to be described below. In our hands the antiglobulin method was not satisfactory for demonstrating univalent alpha and beta antibodies.

Before describing the actual techniques used a few general remarks are necessary, in view of the continued appearance of reports claiming extravagant titers as high as 82 million units.<sup>24</sup> With the methods used in our laboratory we have hardly ever obtained titers as high as or higher than ten thousand units. The excessive values reported in the literature are probably explained by faulty technique especially by carrying over when making serum dilutions. To avoid this pitfall we use separate tubes of saline in order to rinse the pipet thoroughly between dilutions. When extraordinarily high titers are obtained the titrations are repeated starting with an accurately prepared dilution of the serum e.g. 1 to 10 or 1 to 100, depending on the titer expected. Moreover a different pipet is used for each serum and each blood suspension. The titer is taken as the reciprocal of the highest dilution giving a one plus reaction. A typical titration should end somewhat so the following fashion ++ + + + + ± + +, + ± +, +, +, —. On the other hand if the titration ends so the following manner ++ + ± + + ±, ± + +, —, the technique is suspect and the titration should be repeated instead of taking the last one plus reaction as the end point. To consider hardly distinguishable reactions such as the trace or ± level as the end of a titration is certainly unsafe and this probably accounts for some of the false high titers reported in the literature.

The maximal agglutination titer which may reasonably be expected to exist can be determined by converting agglutinin titers into milligrams of antibody protein per cc. This has been done in detail by Barrett and Tripp<sup>25</sup> for bacterial agglutinins while Kabat and Bezer<sup>26</sup> have made similar determinations for alpha hemagglutinins by the method of precipitation using as the antigen a solution of purified A substance. For example these latter workers have found that an anti A serum with a titer of 512 units contains about 60 micrograms of antibody nitrogen per cc. This estimate appears to be conservative when one considers that red cells have about 8 to 16 times the diameter of bacterial cells so that a titer of 512 for red cells should correspond to a titer of 64 for bacterial antigens or about 500 micrograms of antibody nitrogen per cc. according to the work of Barrett and Tripp. Using the more conservative estimate table 1 was constructed. It will be seen that a titer of 16 000 units which is the maximum that has ever been encountered by this laboratory corresponds to about 12.4 mg. antibody per cc. or about 1.2 grams per cent. This would mean that about one half to one third of the serum globulin would have to be in form of antibody which is not an unreasonable concentration for highly immunized individuals. In the right half of the table are listed some of the higher titers examples of which have been reported in the literature. It will be seen that the highest titer claimed namely 82,000 000 units would imply a serum containing about 60 grams of protein in the form of antibody per cc.

For titrating alpha and beta antibodies fresh blood suspensions of groups A<sub>2</sub> and B were used routinely and in some cases also blood of subgroup A<sub>1</sub>. Group O blood was always included as a check on

\* Under ideal conditions the antiglobulin test of Coombs et al.<sup>14</sup> and Moreschi<sup>15</sup> gives titers about two to four times as high as the albumin plasma technique.

† Perhaps the method of fractionating Rh antibodies by dialysis devised by Witelsky et al.<sup>17</sup> could be applied successfully also to alpha and beta antibodies.

the specificity of the reactions. Saline suspensions were prepared washed once by centrifugation, and the sediment resuspended to make a 2 per cent suspension. Into each tube (7-8 mm inside diameter) in a series was placed a drop of a corresponding series of progressively doubled dilutions of the serum to be titrated e.g. undiluted  $\frac{1}{2}$ ,  $\frac{1}{4}$ ,  $\frac{1}{8}$ , etc. When titrating alpha antibodies a drop of suspension of blood of subgroup A<sub>2</sub> (or occasionally also A<sub>1</sub>) was added to each tube while group B cells were used for titrating beta antibodies. The mixtures were shaken and placed in a water bath or incubator at 37 C for one hour. The tubes were then gently shaken and the reactions read with the naked eye and checked under the low power of the microscope. The results of this reading constituted the saline or agglutination titer. To each tube was then added a drop of the acacia solution described below and the mixture shaken and re-incubated for another hour. The results of the reading after the second hour constituted the acacia-conglutination titer. A duplicate titration was set up in saline media at the beginning of the first hour, and after the cells had sedimented completely all of the supernatant fluid was removed from each tube with the aid of a fine capillary pipet. To each tube was then added a drop of oxalated plasma, group A plasma

being used for the alpha titrations and group B plasma for the beta titrations. The cells were resuspended the mixtures incubated for a second hour and the reactions read. The results of this test were designated the plasma-coagglutination titer.

The solution used for the acacia-conglutination titration was prepared by dissolving 10 grams of gum acacia and 1 gram of dibasic sodium phosphate ( $\text{Na}_2\text{HPO}_4$ ) in 90 cc of distilled water and sterilizing at once in the autoclave at 10 pounds of pressure for ten minutes.<sup>21</sup> The resulting opalescent solution is usable for a long time if kept sterile. It is important not to use too much heat when sterilizing or else the solution will not be active. Presumably excessive heating splits the acacia as indicated by the observation that such preparations are less viscous and more transparent instead of opalescent.

### CASE REPORTS

**Case 1.** The mother of this patient was referred to us because in routine antenatal tests she had been found to be Rh negative and her husband Rh positive. Her first pregnancy had terminated one year previously with the birth of a 7 pound 4 ounce infant who was delivered two weeks postmaturely after a labor of about eighteen hours. This child exhibited neither jaundice nor anemia and is now alive and well. The mother had never received any blood or plasma injections. The mother when first seen was entering the second trimester of her second pregnancy.

Grouping and Rh Hr tests done on the prospective parents and the first child gave the results shown in table 2. Also included in table 2 are the results of the saliva tests done on the family at a subsequent date.

Tests for Rh antibodies done on the mother's serum at this and subsequent examinations gave negative results by the agglutination method and the albumin plasma and acacia conglutination technics so that it was clear that she was not sensitized to the Rh factor. In view of the incompatibility to the major blood groups, the alpha and beta antibodies in the mother's serum were titrated. The results of these tests are shown in table 3 which lists the titers of alpha and beta antibodies as determined by the agglutination method and by the plasma and acacia-conglutination methods at various intervals throughout the remainder of her pregnancy. In view of the extraordinarily high anti B titer (average about 2-4 thousand units) we felt that she was carrying a group B fetus (cf Polayes et al<sup>11a</sup>) who might well prove to be erythroblastotic but on the basis of B sensitization rather than Rh sensitization.

The mother went into spontaneous labor at term and delivered a 7 pound 4 ounce male infant who appeared to be normal except for some cyanosis of the extremities and very mild jaundice. Examination

of the cord blood revealed that the hemoglobin concentration was 11 grams per cent and the white blood cell count 31,450 per cu. mm. There were 22 nucleated red blood cells per 100 white blood cells on the smear. The icterus index was 36 units. The infant was found to belong to group B type MN type Rh<sub>+</sub>. Despite the fact that the baby belonged to group B it was possible to demonstrate free beta antibodies in addition to alpha antibodies in its serum by the slide technic—an unprecedented finding up to that time in our own experience.

In view of these observations there was no doubt that the baby had erythroblastosis fetalis but due to B sensitization rather than to Rh sensitization in accordance with the prediction. It was therefore decided to treat the infant with exchange transfusion using blood of group O. One group O Rh negative and one group O Rh positive donor were selected each of whom had low titers of anti B agglutinins in his serum. The Rh positive donor was selected as a control in order further to test the conclusion that Rh sensitization had nothing to do with the patient's illness. By the time the preparations for the procedure were completed the jaundice had increased markedly (the icterus index determined subsequently proved to be 64 units by the acetone method as against 36 units at birth) and several petechiae had appeared on the face.

Five hundred cc. of blood were drawn from each donor into 60 cc. of citrate solution and this fresh

blood mixed with 10 cc. of a solution of A and B group substances\* was used for the transfusion. A total of 920 cc. of the citrated blood was introduced into the saphenous vein at the ankle while 820 cc. of blood were removed from the radial artery at the wrist over a period of 2 hours and 40 minutes. Heparin was used in the usual way to facilitate the bleeding, and calcium gluconate injected in fractional doses to counteract the effect of the citrate injected. The baby withstood the procedure well.

The following morning the baby's color was good and there was hardly any noticeable jaundice. The blood count at that time was hemoglobin concentration, 15.9 grams per 100 cc., and white blood cell count 12,400 per cu. mm. Two days after the transfusion progress seemed to be satisfactory except that edema of the legs and dorsum of the feet was noted. This subsided within twenty-four hours. On the third day the blood count was as follows: hemoglobin concentration 17.4 grams per 100 cc., red blood count 5.8 million per cu. mm., white blood count 11,700 per cu. mm., polymorphonuclear leukocytes 77 (24 band forms), myelocytes 5, monocytes 6, eosinophiles 12, non-nucleated red blood cells were seen on the smear. (As has been pointed out previously<sup>2</sup> the eosinophiles are regarded as due to the presence of an antigen-antibody complex in the infant's body.) The remainder of the baby's stay in the hospital was uneventful. A blood count done on the sixth day showed that the hemoglobin concentration was 14.1 grams per 100 cc., the red blood count 4.8 million per cu. mm. and the white blood count, 13,250 per cu. mm. Differential count showed polymorphonuclear leukocytes 33 (8 band forms), myelocytes 2, eosinophiles 17, lymphocytes 44, and monocytes 6. On the eighth day the percentage of eosinophiles had fallen to 2, and on the eleventh day the infant was discharged.

When the baby arrived home diarrhea developed with loss of weight down to 5 pounds 14 ounces at the end of three days. The diarrhea was treated at another hospital with starvation, parenteral fluids and blood transfusion. It is of interest to note that at that hospital the baby was typed as group O and that the transfusionist refused to accept our word that the infant really belonged to group B. As a result the infant continued to receive group O blood. It was not until the baby was seven weeks old that the diarrhea was under control and the baby regained its birth weight of 7 pounds.

The infant's subsequent physical and mental development has been normal. He held his head up at the age of 3 months and sat at 6 months. When seen again at the age of 10 months he weighed 23 pounds, was 30 inches long and was beginning to walk. His general demeanor was bright and he was responsive to his environment.

Of particular interest were the comparative studies of the antibody content of the maternal and infant's serum at birth, and the subsequent course of the antibody titers in the baby's serum after delivery. As shown in table 4, the baby not only had free alpha antibodies in his serum but also had substantial amounts of free beta antibodies despite the fact that he belonged to group B. Ordinarily, any beta antibodies passing into a group B fetus would be expected to be absorbed by the baby's cells and body fluids, leaving no free antibodies in the plasma. Only when a large excess of antibodies filters into the fetal circulation can free incompatible antibodies be expected to be demonstrable in the baby's serum, just as occurs in severe erythroblastosis due to Rh sensitization. Judging from the amount of univalent alpha antibodies present in the baby's serum, namely, about 100 units, one could estimate that  $\frac{1}{3}$  to  $\frac{1}{2}$  of the maternal alpha antibody titer in plasma or acacia medium represents univalent antibody. If we assume the same proportion for the maternal beta antibodies, one could postulate a titer of about 500 to 1,000 units of beta univalent antibodies capable of filtering through the placenta, so that the presence of 80 units of free beta antibody in the baby's serum does not seem excessive under these conditions.

That these babies are not killed outright by the incompatible antibodies may

\* Obtained from Sharpe and Dohme.

seem remarkable at first sight. However, at least two protective mechanisms\* appear to exist which prevent such an outcome, namely, the low concentration of *conglutinin* in the fetal plasma<sup>16-22</sup> and the differences in sensitivity between the red cells of the newborn and those of the adult.<sup>23</sup> Univalent antibodies coat the cells of the infant, but without the aid of the third component, *conglutinin*, cannot clump them, so that until the process of maturation provides sufficient *conglutinin* the disease is held in abeyance. The lower sensitivity of the fetal red cells serves to work in the same direction. The titrations reported here were carried out with red cells obtained from *adults* and not with blood from infants, so that the titers are actually somewhat misleading. In fact, tests of the baby's plasma against its own red cells did not produce clumping even in the presence of adult plasma or *acacia*, indicating that the unabsorbed free beta antibody in its plasma represented

\* The reactions indicated by asterisks though occurring in saline media, are probably due to *conglutination* rather than *agglutination* similar to the phenomenon sometimes noted when titrating *trivalent* Rh antibodies in saline media.

that component incapable of reacting with its own group B red cells. It will be noticed that the antibodies disappeared relatively rapidly from the baby's circulation, as indicated by the much lower titers found at the age of one week, at which time the excessive numbers of *cosinophiles* also disappeared.

When the baby was born, 10 cc of a solution of group substances had been introduced into his umbilical vessels. This had no appreciable effect, however, in arresting the progress of the disease, so that the exchange transfusion was carried out. It will be seen, moreover, that despite the injection of group substances there was only a partial reduction in the antibody titers between the time the baby was born and the time the transfusion was started. Tests done later on showed that the baby was a *secretor*. The observations in this case as well as in others (cf. page 1028), therefore, indicate that *Levine's* assumption<sup>25</sup> that maternal alpha and beta antibodies affect only babies who are *nonsecretors* is not correct. This phase of

\* The possible existence of other protective factors in the body of the fetus and newborn may prove a profitable field for investigation.<sup>1-24</sup>

the pathogenesis of erythroblastosis fetalis caused by A and B sensitization will be discussed in greater detail later on

*Case 2* The mother of this baby was first seen by us in October 1946 when she was referred for grouping and Rh Hr tests because of the following history. She had never received any injection of blood or plasma and had had only a single pregnancy which terminated on December 6, 1943 with the birth of a male child. This first baby became jaundiced 24 hours after birth and was given a blood transfusion when he was a few days old. He was still jaundiced at the age of nine days when he was discharged from the hospital and the parents remarked that the jaundice persisted for several weeks at home. This child is alive and well and has no sequelae of his neonatal illness. Grouping and Rh Hr tests done on the family at the time of the first visit gave the results shown in table 5.

These results proved that the Rh factor had nothing to do with the baby's illness and suggest that sensitization to the agglutinin A might be the cause. Evidence supporting this surmise was obtained by titrating the maternal alpha and beta antibodies when it was found that the titer of alpha antibodies

August 11, 1948 (35 weeks)	56	150	300	20	40	100

was considerably elevated especially by the coagulation method (cf table 6) despite the long interval of almost three years since the child had been born.

The mother became pregnant for the second time in 1947 but this pregnancy terminated in a spontaneous abortion at two months. She became pregnant for the third time in 1948 and was retested in June 1948 when her pregnancy had progressed to 27 weeks. At that time titrations of the alpha and beta antibodies showed that their titers had fallen considerably (cf table 6). One month later there was some increase in titer but not to an alarming degree.

The patient a female infant weighing 8 pounds 13 ounces was delivered spontaneously at term. Jaundice was present at birth although the baby appeared to be normal otherwise. A blood count revealed a hemoglobin concentration of 16.9 grams per 100 cc, an uncorrected white blood cell count of 21,500 per cu mm, 44 per cent polymorphonuclear leukocytes of which 14 were band forms, 50 lymphocytes, 6 monocytes and about 100 nucleated red blood cells per 100 white blood cells on the smear. Examination of the cord blood showed that the infant belonged to group A and that the cord serum had an icterus index of 44 units by the acetone method. Moreover while the baby's cells formed a smooth suspension in saline they clumped spontaneously when suspended in plasma or acacia. Although the baby belonged to group A free alpha antibodies could be demonstrated in her serum by the coagulation method. In view of these findings a diagnosis of erythroblastosis due to sensitization to the agglutinin A was made and 10 cc of a solution of A and B group substance were administered intravenously.

During the forty-eight hours following birth there was a slight drop in hemoglobin to 13.5 grams per 100 cc and the blood smear then showed only 17 nucleated red blood cells per 100 w b c. However, the jaundice increased markedly so that the icterus index reached 12.8 units by the acetone method. A second injection of group substance was given, and in view of the progressive nature of the disease it was decided to do an exchange transfusion using group O donors.

Accordingly 500 cc of blood were drawn from each of the two group O Rh positive donors into 60 cc of sodium citrate solution. To each bottle of blood were added 10 cc of a solution of A and B group substances. Nine hundred cc of citrated blood were introduced into the baby by way of the saphenous vein at the ankle while 800 cc were removed through the radial artery over a period of two hours. Heparin was used to facilitate the bleeding and calcium gluconate was injected in fractional doses to counteract the effect of the injected citrate. The baby withstood the procedure well. By the following morning the jaundice had appreciably diminished. However six hours following the transfusion, the baby's temperature rose to 103 F and remained elevated for 48 hours. No abnormal physical findings were detected to account for the rise in temperature. The patient was given routine prophylactic penicillin injections, 20,000 units every three hours, as is done with all infants following exchange transfusion but because of the rise in temperature this was continued for three days instead of the usual twenty-four hours.

By the time the baby was one week old there was no further evidence of erythroblastosis. The icterus index had fallen to 4 units and the patient was discharged from the hospital on the eighth day of life. At the age of 12 days the baby was well. The hemoglobin concentration was 13.4 grams per 100 cc, the red blood cell count was 4.51 million per cu mm and the white blood cell count 8,200 per cu mm. Polymorphonuclear leukocytes 31 (3 band forms), lymphocytes 35, monocytes 10, eosinophiles 4, only 1 late normoblast per 10 w b c on the blood smear. The icterus index was 4 units and the baby's blood reacted as group O, there being no trace of its own group A blood demonstrable. The baby was last seen at the age of four months when she was perfectly well and exhibited no sequelae of her illness.

That this baby was so severely affected came somewhat as a surprise, in view of the relatively low titers obtained in the antenatal titrations of the alpha antibodies in the maternal serum. A test made on the mother on the day of delivery showed, however, that there had been a substantial increase in the alpha antibody titer of the maternal serum (cf table 7), particularly by the agglutination technic, and this explained the findings in the baby. In this case as in the previous one, the injection of A and B group substances had no noticeable effect in arresting the progress of the disease, and there was only a rather disappointing drop if any, in the titer of univalent alpha antibodies in the baby's serum (cf table 7). Therefore, exchange transfusion was resorted to, and the clinical improvement which followed was so prompt and dramatic that there can be hardly any doubt that the baby's rapid recovery was due to the transfusion.

The alpha antibody titers were followed in the baby, and in tests made nine days after birth it was found that the antibodies had almost entirely disappeared (cf table 7). On the other hand, tests done on the mother's serum showed no significant change in titer. It is important to point out that at the end of the transfusion the baby still had significant amounts of alpha antibodies in its plasma. Despite this, her clinical condition improved, indicating that the alpha antibodies *per se* are not toxic to a group A baby in the absence of group A cells with which they can combine. Thus, the antibodies apparently produce organic damage only through the blood stream, presumably by clumping the cells and blocking the circulation, and contrary to the assertion of some workers, do not react directly on the organ cells<sup>18</sup> by virtue of the specific antigens that such cells are supposed to contain.

## NORMAL BABIES AND THEIR MOTHERS

The two cases which have just been presented raise the question as to what findings are obtained when group O mothers have normal group A and group B children, i e., without clinical jaundice or anemia. If we are to ascribe significance to the high antibody titers obtained in these two cases, it is necessary to demonstrate that the titers in normal cases are appreciably lower.

Until recently, no studies had been made concerning univalent alpha and beta antibodies in normal individuals, in fact, until the Rh blocking antibody was found it was not appreciated that such antibodies existed at all. It was generally accepted that the natural alpha and beta antibodies were agglutinins reacting

\* These reactions probably represent conglutination rather than agglutination (cf. footnote to table 4)

better at refrigerator than at body temperature.<sup>37</sup> These alpha and beta agglutinins were supposed to develop spontaneously in the serum as a sort of maturation process of the normal serum globulins, and were not considered to be the result of immunization. Individuals of all four blood groups were believed to produce both alpha and beta agglutinins, but the incompatible antibodies were supposed to be neutralized as quickly as they formed. That the normally maturing globulin should have alpha and beta specificity did not appear entirely surprising, when one considered that globulins having such specificity could also be obtained from bean extracts.<sup>38</sup> Therefore, the idea seemed reasonable that the natural alpha and beta agglutinins are normal serum globulins of large molecular size, and therefore incapable of traversing the placental barrier and doing harm to the baby should it belong to any incompatible group. Consequently, when a baby of an incompatible group developed jaundice and anemia, this was ascribed<sup>13</sup> to the presence in the maternal serum of *univalent* alpha and beta antibodies, presumably the

result of iso-immunization. These concepts have to be modified somewhat in the light of findings which are now to be presented.

In table 8 are listed a random series of cases in which mothers had normal babies belonging to compatible blood groups. It will be seen that the titers of the alpha and beta antibodies in these mothers are in an entirely different range from the titers exhibited by the mothers of the two babies treated by exchange transfusion, and as would be expected, the icterus indices of the cord serums were also within the normal range for newborn infants. The ratios between the titers of the alpha and beta antibodies in the maternal and infant's serums vary according to the method of titration used. In only a minority of instances was it possible to demonstrate the presence of antibodies in the infant's serum by the agglutination method (in saline media), and then in such low titer as to suggest that these reactions were actually due to conglutination\* rather than agglutination. By the conglutination method, in both plasma and acacia media, closer agreement is found between the maternal and infant's titers, and in some instances the titers are even equal. According to these findings, as well as evidence presented elsewhere,<sup>20</sup> it would appear that the antibodies present in the infant's serum at birth are always glutinins (univalent antibodies) derived passively from the mother, and that the maternal alpha and beta antibodies are usually mixtures of univalent antibodies (glutinins) and bivalent antibodies (agglutinins) rather than pure agglutinins. The proportion of glutinins to agglutinins seems to vary from person to person. In occasional instances, the alpha and beta antibodies are not demonstrable, or only barely so, in the baby's serum despite a substantial titer of antibodies in the maternal serum, presumably because the latter are essentially pure agglutinins which cannot traverse the placental barrier.

In view of these findings it is evident that the concept that natural alpha and beta antibodies are always pure agglutinins must be discarded, since a large proportion of normal individuals possess univalent alpha and beta antibodies as well. If we wish to adhere to the concept that univalent antibodies are produced as the result only of active sensitization, the question would arise as to how such sensitization could be produced against the A and B factors. In the course of a life-time it is not difficult to imagine how A and B factors could be introduced into the body through food, or infection, or vaccines administered for protective immunization, in view of the ubiquitous nature of A-like and B-like antigens.<sup>12, 27</sup>

Since many normal individuals possess univalent alpha and beta antibodies

\* The assertion that the antibodies in the infant's serum at birth are always glutinins (univalent antibodies) may seem to be contradicted by the numerous studies in the literature including some of our own earlier papers<sup>22, 40</sup> dealing with alpha and beta agglutinins in the serum of newborns. However, before the Rh blocking antibodies were found it was not appreciated that univalent alpha and beta antibodies existed and so any clumping of A or B specificity was assumed to be agglutination and to be produced by agglutinins. In retrospect there seems hardly any doubt that in our earlier studies we were actually dealing with conglutination and not with agglutination. Under favorable conditions conglutination sometimes occurs in saline media. For example, while American workers found Rh agglutinins 10 less than half the mothers of erythroblastotic babies, British workers reported that about 95 per cent of the sera from such women contained Rh agglutinins. We now know<sup>22</sup> that the British workers were dealing with conglutination which occurred in their tests despite the use of saline blood suspensions.

capable of traversing the placental barrier, it might be expected that when the mother carries a fetus of an incompatible blood group hemolysis of the fetus's cells should be inevitable. As already pointed out, however, the principal protective mechanism in the baby seems to be the relatively low sensitivity of the A and B agglutinogens of the newborn's red cells, so that only when the univalent

alpha and beta antibody titers of the mother reach extraordinarily high levels does harm to the baby result. A remarkably similar situation exists in cattle as has been recently found by Yeas.<sup>41</sup>

For purposes of comparison we have listed a series of antibody values obtained in cases in which mothers had normal babies of incompatible blood groups (cf table 9). It will be noted that the titers were within normal limits in every

instance except one (case 8), in which a group B baby of an O mother was apparently unaffected despite a relatively high titer of beta antibodies in the maternal serum. Here one may postulate that the beta antibodies were almost entirely of the bi valent variety.

#### STATISTICAL EVIDENCE CONCERNING THE ROLE OF THE A-B FACTORS IN ICTERUS PRECOX

One of the reasons why the role of isosensitization to the A and B agglutinogens in producing fetal and neonatal morbidity and mortality was not recognized earlier is that the manifestations usually are mild, and cases such as those described at the beginning of this article are rare. In typical cases, the baby develops only a mild jaundice, usually on the first or second day of life, and there may be a slight fall in the hemoglobin concentration. The disease is then arrested and recovery usually occurs without treatment in four to five days, although in more severe

TABLE 10—*Relative Frequency of Compatible and Incompatible Matings in Relation to the Clinical Manifestations in the Fetus and Newborn*

\* These comprise all normal and abnormal infants not included in the other categories.

cases one or more blood transfusions may be required. This syndrome has been designated *icterus precox* by Halbrecht,<sup>8</sup> in order to distinguish it from so-called physiologic icterus. Among 60 cases of this type, Halbrecht found that in 57 (95 per cent) the blood group of the infant was incompatible with that of the mother, in contrast with the frequency of only 26.5 per cent incompatible in infants among 2,000 normal maternity cases. This finding has been confirmed by Wiener et al.<sup>12</sup> who found that 34 (or 81 per cent) of 42 infants with mild jaundice and anemia belonged to blood groups incompatible with those of their mothers.

When the blood of the child is not available for testing, statistical data concerning the role of the A and B factors may be gathered by comparing the blood groups of the father and the mother. If the father's blood group is incompatible with that of the mother, the mating is said to be incompatible; if the father's blood group is compatible, the mating is said to be compatible. In table 10, we have indicated the relative incidence of incompatible and compatible matings in a variety of clinical conditions including *icterus precox*, typical erythroblastosis, and repeated abortions. Among normal pregnancies the expected incidence of incompatible matings is about 35 per cent. In contrast to this, among 94 cases of

unexplained neonatal jaundice and anemia, as many as 79.8 per cent of the matings were incompatible, indicating that A-B sensitization must have played a part in at least a majority of these cases. On the other hand, among 282 families with erythroblastotic infants due to Rh sensitization only 17.8 per cent of the matings were incompatible, indicating that group incompatibility of the infant's blood reduces the likelihood of sensitization to the Rh factor.\* Incidentally, in patients with two or more unexplained early abortions the incidence of incompatible matings is 52.7 per cent, which is higher than the frequency of incompatible matings in the normal population, and suggests that a certain percentage of these may perhaps be due to A-B sensitization as has been previously pointed out by Levine<sup>35, 44</sup>

#### THE SECRETOR TYPE IN RELATION TO A-B SENSITIZATION

In order further to test Levine's theory that A-B sensitization occurs only in babies of the nonsecretor type, the saliva specimens were examined in a series of 14 families with typical serologic and clinical findings of erythroblastosis due to A or B sensitization. The findings on these families are listed in table 11. It will be seen that all of the affected babies in these families were secretors, which would seem to disprove Levine's contention. Of particular interest are families 6 and 7 in which the babies are secretors even though the fathers are nonsecretors.

Our results suggest that it is actually a disadvantage for the baby to be a secretor since this increases the likelihood of sensitizing the mother (cf. Smith<sup>45</sup>). Presumably the group substances in solution in secretions could traverse the placental barrier more readily than intact red cells. Moreover, smaller amounts of solutions containing group substances are sufficient to sensitize than are intact red cells. For example, as little as 0.2 cc. of autoclaved saliva administered intramuscularly can stimulate a rise in isoagglutinin titer.<sup>46</sup>

Parenthetically, the cases listed in table 11 show a remarkably high incidence of cerebral sequelae. It will be important to ascertain if this is maintained in a larger series of cases of A-B sensitization.

#### COMMENT

Summarizing the evidence which has been presented concerning the pathogenesis of erythroblastosis due to A-B sensitization, the first requisite is that the maternal serum contain univalent alpha or beta antibodies. A high percentage of normal individuals possess such univalent alpha and beta antibodies, but they are usually of only moderate or low titers. In cases of Rh sensitization, even a weak univalent Rh antibody is often sufficient to cause disease in an Rh-positive fetus, though the severity is correlated with the height of the antibody titer. On the other hand, that a low or moderate titer of univalent alpha or beta antibodies is usually relatively harmless to the infant suggests the presence of a special protective mechanism

\* It was previously suggested by one of us<sup>42</sup> that this phenomenon could be explained on the basis of competition of antigens. Another plausible explanation is that any group incompatible fetal blood which might leak into the maternal circulation would be rapidly eliminated before Rh sensitization could take place.<sup>43</sup>

Case No	Father	Mother	Pregnancies
1*	BMRh <sub>0</sub> Secretor	OMNRh (No anti Rh in serum)	1 BMNRh <sub>0</sub> ♀ secretor, normal. 2. BMNRh <sub>0</sub> ♂, secretor, erythroblastosis, treated by exchange transfusion.
2	A <sub>1</sub> MNRh <sub>1</sub> rh Secretor	OMNRh <sub>1</sub> Rh <sub>2</sub>	1 OMNRh <sub>1</sub> rh♀, normal 2. A <sub>1</sub> MNRh <sub>1</sub> rh♀, secretor jaundice, treated with transfusion.
3	A <sub>1</sub> MNRh Secretor	OMNRh <sub>0</sub>	1 AMNRh <sub>0</sub> ♂ secretor jaundice 2nd day moderate anemia, recovered without treatment
4	BMRh <sub>1</sub> Secretor	OMNRh <sub>1</sub>	1 Premature twins both♀ one stillborn. Other twin, BMRh <sub>1</sub> rh secretor, jaundice and anemia, transfused 4 times microcephalic and amaurotic, idiotic, died at 5 years
5	BMNRh Secretor	OMNRh <sub>1</sub> Rh <sub>1</sub>	1 BMRh <sub>1</sub> rh♂ secretor, normal 2. Macerated stillborn ♂ 3 BMNRh <sub>1</sub> rh♂ secretor jaundice, mild anemia transfused once, recovered.
6	A <sub>1</sub> MRh <sub>1</sub> Rh <sub>1</sub> Non secretor	OMNRh <sub>1</sub> rh	1 A <sub>1</sub> MNRh <sub>1</sub> rh♂ secretor, normal 2. A <sub>1</sub> MNRh <sub>1</sub> rh♂ secretor jaundice and anemia transfused 4 times, recovered completely
7	A <sub>1</sub> BMNRh <sub>1</sub> rh Nonsecretor	OMNRh <sub>1</sub> rh	1 A <sub>1</sub> MRh <sub>1</sub> rh♀ normal 2. AMRh <sub>1</sub> rh♀, secretor slight jaundice, recovered spontaneously
8	BNrh Secretor	OMNRh <sub>1</sub> rh	1 BMNRh♂ secretor normal 2. BMNRh <sub>1</sub> rh♂ secretor jaundice anemia, transfused recovered
9	A <sub>1</sub> MNRh <sub>1</sub> Rh <sub>2</sub> Secretor	OMRh <sub>2</sub> rh	1 OMNRh <sub>2</sub> Rh <sub>2</sub> ♂, normal. 2. OMRh <sub>1</sub> rh♀ normal 3 A <sub>1</sub> MNRh <sub>1</sub> rh♀ secretor jaundiced 2nd day transfused 2 times subsequently exhibited mental retardation
10	A <sub>1</sub> MNRh Secretor	OMNRh <sub>2</sub> rh	1 A <sub>1</sub> MRh <sub>2</sub> ♂ secretor jaundice, transfused once recovered completely 2. Jaundiced died on the 5th day
11	A <sub>1</sub> MRh <sub>1</sub> Rh <sub>1</sub> Secretor	OMNRh <sub>1</sub> rh	1 A <sub>1</sub> MRh <sub>1</sub> rh♀ secretor anemia and mild jaundice transfused 3 times, complete recovery
12†	A <sub>1</sub> Mrh Secretor	ONRh <sub>1</sub> Rh <sub>1</sub> (No anti hr' in serum)	1 A <sub>1</sub> MNRh <sub>1</sub> rh♀, secretor, normal. 2. OMNRh <sub>1</sub> rh♂, normal 3 A <sub>1</sub> MNRh <sub>1</sub> rh♀, secretor normal 4. A <sub>1</sub> MNRh <sub>1</sub> rh♂ secretor jaundiced 2nd day Icterus index = 160 units recovered. 5 A <sub>1</sub> MNRh <sub>1</sub> rh♀ secretor jaundice and anemia, treated by 2 exchange transfusions recovered
13	A <sub>2</sub> BMNRh <sub>2</sub> Non secretor	OMNRh <sub>2</sub> rh	1 BMNRh <sub>2</sub> ♂ secretor normal 2. BMNRh <sub>2</sub> ♂, secretor, jaundice, transfusion recovered
14	A <sub>1</sub> BMRh <sub>1</sub> rh Secretor	OMNRh <sub>1</sub> rh	1 A <sub>1</sub> MRh <sub>1</sub> rh♂ secretor neonatal jaundice lasting 3 days recovered completely 2. A <sub>1</sub> Mrh♀, secretor jaundice and anemia transfused once subsequently exhibited mental and physical retardation.

\* Same as case 1 reported in detail at beginning of paper

† For clinical details concerning this case we are indebted to Dr Irving L. Samuels of the Grasslands Hospital Valhalla N. Y.

This appears to consist primarily in the incomplete state of development of the A and B agglutinogens in the red cells of the newborn infant or fetus. In contrast, the Rh-Hr agglutinogens are fully developed at birth.

Some recent unpublished observations suggest a second consideration which may possibly contribute to the difference in behavior of cases of erythroblastosis due to A and B sensitization as compared with those caused by Rh sensitization. Specific alpha and beta antibodies may be classified in two different categories, namely, homospecific and heterospecific. Homospecific antibodies can be defined as those produced by injecting animals or human beings with the identical antigen subsequently to be used in the *in vitro* tests. Injections of a foreign antigen sometimes stimulate heterospecific antibodies which cross react because of the structural similarity of the two different antigens. For example, homospecific anti-A serum can be produced by immunizing human group B or group O individuals with group A blood, while heterospecific anti-A serum can be produced by injecting rabbits with sheep blood which contains an antigen chemically related to human A substance. The homospecific antibody presumably fits the corresponding antigen precisely, in the manner that a key fits its corresponding lock, while a heterospecific antibody can be conceived as fitting the antigen like a skeleton key would fit a number of locks of related structure. It seems probable that the combination of a homospecific antibody with its corresponding antigen would be much more avid than that of a heterospecific antibody, so that the latter could possibly be more readily eluted or washed off.

It is characteristic of icterus precox that the firstborn is often affected, and this fits well with the observations presented in this paper demonstrating that univalent alpha and beta antibodies occur in the majority of normal individuals. As has already been pointed out, these are presumably of heterospecific origin, which might partially account for the benign nature of the syndrome. On the other hand, the Rh antibodies responsible for typical erythroblastosis are invariably of homospecific origin, which, in accordance with this hypothesis, would explain the severity of the manifestations. Continuing in the same vein it would be expected that when the alpha and beta antibodies are homospecific, they could also produce severe erythroblastosis. Thus, in our Case 1 treated by exchange transfusion, the first group B baby was normal while the second group B baby was severely affected, presumably due to the active immunization of the mother to the B agglutinogen of the first baby. The second case is even more interesting because the first group A baby was only moderately affected (icterus precox) due to preformed univalent heterospecific alpha antibodies in the maternal serum, while the second baby was severely affected due to active sensitization of the mother resulting after the birth of the first group A baby, with the formation of homospecific alpha antibodies. Further work is in progress to test the validity of concepts.

All of the affected infants tested proved to be secretors, disproving the hypothesis that the disease occurs only in nonsecretors. In fact, the secretor type appears to predispose somewhat to the occurrence of the disease since it increases the chance of sensitization of the mother. A far smaller volume of group substance in solution is required to sensitize than is whole blood. It seems significant that in monkeys

the A and B agglutinogens are lacking from the red cells, but four groups do occur based on the presence of group substances in secretions.<sup>47-48</sup> The evolutionary passage of A and B substances from secretions to the red cells in higher primates may thus be considered as an unfavorable step, since it predisposes to fetal and neonatal death due to A and B sensitization. The mutation which produced the nonsecretor type, presumably at a later date, may be considered as a favorable one, since it reduces the chances of sensitizing the mother. In this connection, it seems significant that the highest incidence of the nonsecretor type is found in negroes,<sup>49</sup> who in many respects are the most highly differentiated members of the human race.

The use of soluble A and B substances for the treatment of A-B sensitization in babies had previously been suggested.<sup>49</sup> However, the results of treatment with these substances in the two cases presented here were disappointing. Actually, this should not be completely unexpected, because before the affected infant is born the antibodies have already been bound by the red cells from which they would be displaced only with difficulty. Our findings do indicate the possibility of anticipating the disease by antenatal tests done on the mother's serum. However, the incidence of typical erythroblastosis due to A-B sensitization is very low, and in most cases the manifestations in the child are mild, so that it would be hardly worth while to include alpha and beta titrations as well as anti-Rh as a routine in all antenatal cases at the present time.

#### SUMMARY

Two unusual cases of severe erythroblastosis due to A and B sensitization have been presented. When injections of A and B group substances failed to arrest the disease, exchange transfusions were carried out, using 900 to 1,000 cc. of fresh group O blood. In each case the response was prompt and dramatic, although the convalescence in one was prolonged by an intercurrent diarrhea. Both infants have made complete recoveries and have developed normally both physically and mentally.

Observations have been presented regarding the pathogenesis of erythroblastosis and icterus precox due to A-B sensitization. The following conclusions seem to be warranted on the basis of the evidence presented:

1. The greatest majority of cases of jaundice and anemia of the newborn that cannot be explained on the basis of Rh incompatibility are caused by incompatibility of the major blood groups.
2. High maternal alpha and beta antibody titers *per se* are not necessarily correlated with disease in the infant.
3. Univalent alpha and beta antibodies present in the maternal serum traverse the placenta and are the cause of the disease in the infant. Bivalent antibodies are held back by the intact placenta and play no or hardly any role in the causation of the disease. Univalent alpha and beta antibodies are demonstrable in the sera of a large proportion of normal individuals.
4. A-B sensitization in pregnancy occurs mainly when the infant belongs to the secretor type.
5. A theory is suggested that the quality of the alpha and beta antibodies

namely, whether they are homospecific or heterospecific, may affect the severity of the manifestations in the infant

Technics of titrating alpha and beta and Rh antibodies are described and discussed. A table has been prepared which converts antibody titers into concentrations of immune globulin in the serum, and demonstrates the impossibility of certain extravagantly high titers claimed in the literature

# THE EFFECT OF STASIS OF BLOOD IN VARICOSE VEINS ON ERYTHROCYTE FRAGILITY, WITH ACCOMPANYING STUDIES COMPARING RED CELLS AND OTHER BLOOD ELEMENTS WITH CUBITAL VEIN BLOOD

By STACY R. METTIER, M.D., JOHN C. WEAVER, M.D., AND  
ALICE F. MCBRIDE, B.A.

IT HAS been demonstrated by Fahræus<sup>1-4</sup> that normal red blood cells have a tendency to become spheroidal in shape after standing in vitro at body temperature. Gänsslen,<sup>5</sup> Haden<sup>6</sup> and Castle and Daland<sup>7</sup> have shown that spheroidal red cells are more susceptible to osmotic hemolysis than are normal corpuscles. Haden found that normal red cells when suspended in graded hypotonic salt solutions become progressively more globular as the solution becomes more hypotonic, and that there is a direct relationship between the volume thickness index and fragility of the red blood cells. Ham and Castle<sup>8</sup> and Tsai, Lee and Wu<sup>9</sup> have further stated that red cell fragility is increased by stasis of the blood in vitro at body temperature. These investigators found that between one-half and two and one-half hours of stasis was necessary before the first manifestation of increased fragility appeared. Spontaneous hemolysis appeared after approximately twelve hours of stasis.

During stasis of blood at body temperature there is also an increase in packed cell volume due to the development of spheroidal cells.<sup>8, 10-11</sup> There is also evidence that under some conditions, in vivo stasis produces increased red cell fragility. Waller<sup>12</sup> and Cermick<sup>13</sup> found an increase in red cell fragility in capillary blood following tourniquet stasis, but Waller found no increased fragility in blood removed from the cubital vein under conditions of stasis except after expressing capillary blood into the veins.

There is evidence that concentration and stasis of red blood cells occur normally in the spleen.<sup>14-16</sup> Red cells obtained from the splenic vein were found to be more fragile when suspended in hypotonic salt solutions than red cells from blood in other veins.<sup>8, 9</sup> As further proof that in vivo stasis may cause red cells to become more fragile, Tsai and co-workers<sup>9</sup> found that osmotic fragility of red cells removed from both the splenic and renal veins increased progressively following stasis produced by occlusion of the veins and arteries of the spleen and kidney.

Ham and Castle<sup>8, 10, 17-18</sup> have attached great importance to the effects of stasis on red cells and consider this factor to be the common denominator in many of the anemias due to hemolysis. They believe that erythrosthesis in the spleen is probably the mechanism producing increased blood destruction in the hemolytic anemias with increased red cell fragility, and also, that an unusual degree of erythrosthesis might account for some hemolytic anemias in which there is normal or secondarily increased red cell fragility. A number of investigators<sup>9, 19-21</sup> have shown that the red cells usually become less fragile to hypotonic salt solutions

following splenectomy Ham and Castle interpret the beneficial effect of splenectomy as being due to the removal of the organ in which a large degree of red cell stasis (and thus increased fragility) occurs. They explain certain anemias associated with splenomegaly on the basis of a probable increase in normal splenic function with respect to erythrostatics.

In an attempt to evaluate further the effect of *in vivo* stasis as a possible mechanism for increasing red cell fragility, the present investigation was undertaken to measure the osmotic fragility of red blood cells from veins in 20 patients without any known hemolytic tendency or other blood dyscrasia. Although the degree of stasis in varicose veins is not known it seems well established that the movement of blood in varicosities is very sluggish. Ochsner and Mahorner<sup>5</sup> visualize the leg with varicose veins as having a circulation of its own. They consider the possibility of a given blood cell remaining in the venous system of the leg indefinitely, coming up each time perhaps to the opening of the saphenous where it again becomes one of the unhappy ones to fall through the opened sluices peripheral in the superficial venous system.

McPheeters and Rice<sup>26</sup> studied the direction of blood flow in leg varicosities and discussed in detail the movement of lipiodol injected into the varicosities of two patients with a positive Trendelenburg test. One subject was recumbent and the other sitting with legs horizontal. In both cases the injected lipiodol remained stationary until the patient tensed the abdominal muscles or moved the feet, following which the lipiodol was seen to move distally. In their experience the dye never moved centrally. However, Schmier<sup>27</sup> and Heller<sup>28</sup> observed that injected radio opaque material moved in a central direction. Heller determined the specific gravity of blood removed from the varicose vein under observation and then injected radio opaque dye of the same specific gravity. He found in patients having varicose veins and competent valves that the circulation was directed centrally but at a slower rate than in the normal control. In patients with incompetent valves the flow was nearly stationary but after the patient remained standing for some time a very slow upward flow developed. Coughing or straining rapidly reversed the flow and forced the opaque substance distally. He also noted that when the patient first stands after being in a supine position there is a surge of blood down the varicose vein. While there is no definite proof that a significant quantity of blood stagnates in the varicose vein for hours it is evident that abnormal erythrostatics does occur.

### METHOD

The patients used in this study had all been previously examined in the Varicose Vein Clinic of the University of California Medical Center. Each patient was requested to stand quietly for a period of at least fifteen minutes. Blood was then drawn from a tortuous dilated superficial vein, usually on the calf, and immediately afterward a similar sample was obtained from the cubital vein without the aid of a tourniquet.

The following studies were made on the two specimens of blood: (1) The osmotic fragility of the red cells. (2) The packed cell volume. (3) Hemoglobin, red blood count, white blood count and platelet count (Rees and Ecker method<sup>29</sup>). (4) Plasma protein (Falling drop method).

All of the laboratory determinations were performed by one of us.

The valves of the long saphenous veins were incompetent in each of the patients tested (Sp, Di, and Wh<sub>1</sub> were not tested). The clinical degree of tortuosity and dilatation of each patient is indicated in table 1. One patient (Di) had a varicose ulcer. There was neither evidence of congestive heart failure nor obvious blood dyscrasia in any of the patients studied.

## RESULTS

1 *Hypotonic fragility* The resistance of the red blood cells to hypotonic solutions of saline was determined on blood from the cubital and varicose veins of 19 otherwise healthy patients. The fragility of the red blood cells from the varicose veins was not significantly different from the fragility of red cells

obtained from the cubital veins (table 1). In each patient the red blood cell fragility fell within the normal range in both the varicose vein and the cubital vein specimens.

2. *Red cell count, packed cell volume, serum protein, hemoglobin, white cell count and platelet count* The increased pressure in varicose veins should cause fluid transudation into the tissues which would be expected to produce hemoconcentration of the varicose vein blood. However, Erb and Tickense<sup>29</sup> found no increase in red cells, red cell fragility, white cells or platelets in blood from varicose veins as compared with cubital vein blood.

(a) Our results show a small but significant increase in red blood cell count in blood from varicose veins as compared with the cubital vein blood. Statistical calculations show  $P < 0.05$ ; the mean difference being 108.5 million red cells. This is indicative of a minor degree of hemoconcentration.

(b) Surprisingly enough the packed cell volume of varicose vein blood was only suggestively higher.

Statistical analyses of our data were made by Dr. John C. Talbot of the University of California Medical Center.

than cubital blood ( $P$  slightly  $< 0.05$ ) If as result of stasis some red cell swelling had occurred some increase in packed cell volume would result and added to a certain amount of hemoconcentration it would be expected that the packed cell volume would increase out of proportion to the red cell increase.

(c) There was a suggestive increase in total serum protein in varicose veins compared with cubital veins ( $P$  somewhat  $> 0.05$ ) A more accurate technic or a larger series would be necessary to establish the significance of this apparent increase

(d) There was no significant difference in hemoglobin platelets or white cells in the varicose and cubital vein samples

### COMMENT

As mentioned earlier, the preponderance of evidence indicates a slow, steady progression of blood centrally in varicose veins with refluxes of blood following straining and coughing and other activities which increase the intra abdominal pressure. It seems likely, then, that the slow movement of blood through varicose veins does not produce stagnation comparable to that which has been shown necessary to produce red cell swelling and increased fragility in the test tube. In an attempt to establish roughly the duration that a measurable quantity of blood remains in the varicose vein, we, in collaboration with Doctors J. Hopper, Jr., and C. J. Mudrick, performed the following experiment:

Evans blue dye (T1824) was injected into a varicose vein of a patient with marked varicosities. No dye appeared in the cubital vein blood until two minutes after the injection. The dye concentration gradually increased and finally leveled off fifteen minutes after the injection. Dye did not appear in the varicose veins of the opposite leg until four minutes following injection and failed to reach the dye concentration of the arm in a period of thirty minutes. It has been shown that dye injected in an arm vein of normal subjects appears in samples of blood taken from the other arm within thirty seconds and levels off within three to four minutes.<sup>21</sup> Obviously our experiment in one patient and without controls has no comparative value but it does indicate that in this patient a certain amount of stasis occurred in the varicosity for about fifteen minutes. Further experiments on this problem are in progress.

Our data permit no final conclusions regarding the importance of the factor of stasis in hemolytic diseases. However, the lack of increased red cell osmotic fragility under the conditions of stasis that occur in varicose veins suggests that erythrosthesis of a moderate degree does not play a major part in most hemolytic diseases. We are inclined to agree with the viewpoint of Dameshek and Miller<sup>22</sup> that the hemolytic states are due to a number of different causes such as hemolysins, agglutinins and inherited red cell abnormalities with such supplementary factors as stasis, trauma, and possibly, chemical and hormonal changes augmenting the occurrence of hemolysis. It seems likely that several factors are operating at once. For example, in the presence of hemolytic disease, increased stasis and increased trauma to the red cells might be expected to produce some increase in the degree of hemolysis. It also seems likely that in order for stasis appreciably to augment hemolysis in any given hemolytic syndrome it is necessary for stagnation to occur over a prolonged period of time. Tsai<sup>9</sup> showed that increased red blood cell fragility did not appear until stasis had been present for one-half hour to two and one-half hours and that hemolysis did not begin until about twelve hours of stasis. Also in

our experiment and in Waller's<sup>17</sup> a degree of stasis beyond that normally existing did not produce a significant increase in fragility in blood from veins. Therefore, the amount of stasis present in congestive failure or produced by increased blood viscosity caused by the increase in globulin in infections as suggested by Castle<sup>8, 17</sup> would hardly seem sufficient to produce hemolysis. It is probable that the spleen is the only organ in the body in which stasis, sufficient to cause a significant increase in hemolysis, might occur.

The absence of a greater degree of hemoconcentration than we found in varicose vein blood is difficult to understand. Beecher<sup>33</sup> found a gross filtration pressure of 50 cm. of water in excess of the colloid pressure of the blood in varicose veins and concluded that normal resorption of tissue fluid at the venous end of the capillary was impossible and all tissue fluid must be carried off by the lymphatics. This should result in marked hemoconcentration but our experiments showed evidence of only mild hemoconcentration. Obviously, factors are involved which have not been adequately explored.

Our results confirm the findings of Erb and Tiefensee<sup>30</sup> that there is no significant increase in white cells, platelets, and red cell fragility in blood from varicose veins as compared with cubital vein blood. However, our finding of a significant increase in red cells in the varicose vein is at variance with their conclusion that the red cells were not significantly higher than in the cubital vein.

#### SUMMARY AND CONCLUSIONS

1. Blood from varicose veins was compared with cubital vein blood in 20 patients in order to determine whether or not the degree of stasis present in varicose veins would increase red cell fragility. Corollary studies consisted of comparative determinations of red cells, hemoglobin, packed cell volume, white blood cells, platelets and serum proteins.

2. There was no increase in red cell fragility in the varicose vein specimen, indicating that the theory that minor degrees of intravascular erythrosthesis contribute substantially to some of the hemolytic anemias is untenable.

3. There was a small but statistically significant elevation in red cells per cu mm in varicose vein blood as compared with blood from cubital veins. There was a suggestive, but not significant, increase in packed cell volume and serum protein in the varicose vein samples. The evidence indicates a mild degree of hemoconcentration.

4. White cells, platelets and hemoglobin determinations were found to have the same values in varicose vein blood as in blood from the cubital vein.

# THE ROLE OF STAPHYLOCOAGULASE IN BLOOD COAGULATION

## I THE REACTION OF STAPHYLOCOAGULASE WITH COAGULASE-GLOBULIN (CG) TO FORM COAGULASE-THROMBIN (CT)

By JOHN B. MIALE, M.D.

THE ABILITY of some strains of *Staphylococcus aureus* to clot oxalated plasma has long been recognized. This phenomenon was first reported by Loch<sup>1</sup> in 1903. Later, Gratia<sup>2-6</sup> concluded that a substance which he called 'staphylocoagulase' was produced by actively growing organisms and that this was the agent responsible for the coagulation of the plasma.

Attempts to define the nature and mode of action of staphylocoagulase have resulted in a great deal of conflicting data. Contradictory findings on the filtrability of this substance through bacterial filters have been reported by Gross,<sup>7-9</sup> Genou,<sup>10</sup> Vanbreuseghem<sup>11</sup> and Walston.<sup>12</sup> Lominski<sup>13</sup> found that he was unable to separate staphylocoagulase from the bacterial cells by filtration through Seitz and Chamberland filters, centrifugation, or by killing the organisms by heat and chloroform and ether vapor. He concluded that staphylocoagulase was formed only in the presence of living organisms and plasma. He therefore prepared what he called staphylocoagulase by adding plasma to the broth culture and filtering through a Chamberland L<sub>4</sub> candle.

The ability of staphylocoagulase to clot purified fibrinogen has also been debated, Much<sup>14</sup> claiming that it did not, while Gratia,<sup>5</sup> Cruickshank<sup>15</sup> and Walston<sup>12</sup> claimed that it did. Some of these conflicting opinions are probably due to the use of impure preparations of fibrinogen.

Smith and Hale<sup>16</sup> were the first to demonstrate the nature of the reaction. They showed clearly that staphylocoagulase could be obtained as a sterile cell-free culture filtrate, and that this was unable to clot fibrinogen unless an accessory factor present in tissue extracts and plasma was added. They termed this accessory factor an 'activator' of staphylocoagulase, and this concept is retained by Ferguson.<sup>19</sup> Lominski and Roberts<sup>17</sup> added the finding of a serum inhibitor, but it must be pointed out that the material which they called staphylocoagulase was not the native staphylococcal product, as is obvious from Smith and Hale's studies and from the data below. As this paper was being prepared, Kaplan and Spink<sup>18</sup> published their studies with living cultures of *Staphylococci* and confirmed and extended the above concepts.

This series of studies is an attempt to define the relationship of this bacterial substance to the mechanism of blood coagulation. The present paper presents data on the nature of the substance elaborated by staphylococci (*staphylocoagulase*) and observations on the nature of plasma factor with which it reacts (*coagulase*).

From the Laboratories of the Marshfield Clinic and St. Joseph's Hospital, Marshfield, Wisconsin.  
This study was aided during 1944-1946 by grants from the University of North Carolina—Watts Hospital Research Fund and since then by the Marshfield Clinic Research Foundation.

globulin, (CG) to form a thrombin-like substance which is referred to as *coagulation-thrombin*, (CI)

## EXPERIMENTAL

### I. Preparation of Staphylocoagulase

For critical experiments it is necessary to work with a sterile cell-free preparation of a known staphylocoagulase titer. Although it is possible to obtain material of higher titer in non-cell free preparations it is best to use staphylocoagulase prepared by the following method.

A suitable strain of *Staphylococcus aureus* is inoculated into 10 cc of Tryptose broth (Difco) and incubated at 37 C for six hours. The entire 10 cc are then inoculated into 500 cc of Tryptose broth, pH 7.4, and incubated at 37 C. for twenty-four hours. During this period, the pH of the culture is checked repeatedly (Beckman pH meter) and the pH maintained as near as possible at 7.0-7.4. After incubation, the culture is then filtered through a Berkefeld V candle and the filtrate (sterility checked) is distributed into smaller air-tight sterile containers and stored in the refrigerator (0-4 C). Very little loss of titer takes place over a period of several months. The titer of staphylocoagulase is determined by the serial dilution method previously described.<sup>20</sup> The quantitative unit of staphylocoagulase which is most useful can be defined as the smallest amount in a volume of 0.5 cc (saline diluent) which when added to 0.5 cc of oxalated human plasma (diluted 1:10 with saline) produces a 4+ clot in twenty-four hours or less.

Attempts to obtain sterile staphylocoagulase by other methods reveal some interesting properties. Attempts partially to clear the whole culture by centrifugation caused a marked drop of the staphylocoagulase titer of the supernate, while on fast and prolonged centrifugation the supernate had a very low titer. The finding by Smith and Hale<sup>16</sup> that staphylocoagulase was fairly heat stable was confirmed for both whole cultures and sterile filtrates, but it should be noted that sterile cell-free filtrates are more heat stable than whole cultures. Furthermore, the whole cultures show a great deal of variation in heat stability, varying with different strains and media. It is possible, therefore, to prepare sterile (but not cell free) staphylocoagulase by this method but, because of the total unpredictability of the results as well as the undesirability to altering proteins by heat, staphylocoagulase prepared by this method was not used.

The reported discrepancies in filterability of staphylocoagulase are apparently due to two factors, the nature of the filter and the pH of the culture. None of the bacterial filters are totally satisfactory since they differ only in degree as to how much staphylocoagulase is retained. The best is the Berkefeld V candle, with UF fritted glass (Corning) second best. Berkefeld N, Chamberland L, Mandler, and Seitz filters give culture filtrates which are almost always lacking in staphylocoagulase activity.

The pH of the solution appears at times to influence the filterability of staphylocoagulase through a Berkefeld V candle. Thus, if the pH of the culture is too high or too low no active filtrates will be obtained, in spite of the finding that the

whole culture has a very high staphylocoagulase titer over a wide pH range (5.0-10.0). The cell-free filtrate requires an optimum pH of about 7.2 for maximum activity, and shows only negligible loss of activity within the pH range of 6.0-8.0. However, the finding that an inactive filtrate from a too acid or too alkaline culture when adjusted to pH 7.2 still fails to show staphylocoagulase activity suggests that the failure is in the filtration. Best results require a whole culture at pH of about 7.2 for filtration through a Berkefeld V candle.

Attempts to preserve whole culture preparations by addition of bactericidal and bacteriostatic substances have also revealed some as yet unexplained phenomena. For example, in attempting to sterilize broth cultures with penicillin the interesting effect illustrated in table 1 was noted. Penicillin was added in increasing unit concentrations to aliquots of a 24 hour Tryptose broth culture of *Staphylococcus aureus*. This strain in broth culture was sensitive to a penicillin concentration of

TABLE 1—Effect of Penicillin on the Coagulation of Plasma by a Broth Culture of *Staphylococcus aureus* (Penicillin G) added to aliquots of a 24 hr. broth culture previously diluted 1:20 with sterile saline. 0.5 cc. of sample added to 0.5 cc. of oxalated human plasma diluted 1:10 with saline. Test at 37°C.

Penicillin Concentration units/cc	Subculture	Clotting
0	Positive	4+ in 15 min
10	Positive	4+ in 30 min
20	Positive	4+ in 2 hours
50	Positive	4+ in 4 hours
100	Positive	3+ in 6 hours
200	Positive	Negative
400	Positive	Negative
800	Positive	Negative
1600	Negative	Negative
3200	Negative	Negative

1600 units/cc, but inhibition of coagulation was partial at 100 units/cc and complete at 200 units/cc. In other cases, the reverse could be demonstrated, that penicillin in higher concentrations than that necessary to kill the bacteria could inhibit the coagulating ability. This inhibition has been reported by Mason,<sup>21</sup> while Agnew, Kaplan, and Spink<sup>22</sup> have recorded the same effect with both penicillin and streptomycin.

Crystal violet in a concentration of 1:100,000 shows inhibition of staphylocoagulase activity of an otherwise strongly positive preparation. The same inhibitory effect is shown by high concentrations of phosphate and borate ions.

#### 11. The Evidence for an Accessory Plasma Factor (Coagulase-Globulin) Necessary for Coagulation

If one adds whole culture of staphylococci to oxalated plasma a variable length of time must elapse before the plasma is clotted. This varies from about fifteen minutes to several hours, depending in part on the concentration and activity of the reagents. Since sterile cell-free staphylocoagulase behaves in the same way, this

antihemophilic globulin Tissue extracts contain a considerable amount of the substance in question, as shown by the activity of rabbit testes extract and thromboplastin from rabbit brain Platelets are, interestingly enough, free of

TABLE 2.—*The Distribution of Accessory Factor (Coagulase Globulin CG) in Plasma Fractions Obtained by Alcoholic Fractionation*

<sup>12</sup> Hemophilic Coagulase Globulin from 100% Ammonium sulphate precipitate of hemophilic plasma.

activity Since it has so far not been related to any of the other globulin factors it seems justified to consider it as a specialized globulin characterized by its reaction with staphylocoagulase, and to designate it as coagulase globulin or CG

### III Preparation of Crude CG Fraction

Advantage is taken of the observation<sup>17</sup> that the 50 per cent ammonium sulphate fractions contain most of the inhibitor substance. To oxalated human plasma is added slowly and with constant stirring an equal amount of saturated  $(\text{NH}_4)_2\text{SO}_4$  solution. After three hours at 0 degrees C, it is filtered at 0 degrees C and the precipitate discarded. The filtrate is treated with dry  $(\text{NH}_4)_2\text{SO}_4$  to saturation and allowed to stand at 0 degrees C for 6-12 hours. After filtration the precipitate is dissolved in the smallest possible volume of cold saline and dialyzed against several changes of saline for 24 hours at 0 degrees C.

TABLE 4—Clotting Time of Oxalated Plasma with Staphylocoagulase and Coagulase Thrombin after Various Treatment

0.5 cc of oxalated human plasma diluted 1:10 with saline and 0.5 cc of material tested, at 37 C. Clotting time is time required for a 4+ clot to form.

7 Plasma 1:1 + CT	clot in 17 min

### IV Properties of Coagulase Thrombin (CT)

By allowing staphylocoagulase to react with CG at 37 C for an optimum time (usually 2-3 hours), a new substance is formed (coagulase thrombin, CT) which is distinctly different in its properties (table 4).

Staphylocoagulase and CG are little affected by exposure to 60 C/30 minutes, whereas, it is apparent that CT is somewhat heat-labile. None of the three is dialyzable, but there is a striking difference in filterability through bacterial filters, staphylocoagulase being retained by most filters while CG and CT are filterable through all of them. All three are fairly stable even in the crude form at refrigerator temperature.

The most striking evidence that CT is different is its ability to clot fibrinogen free of CG, whereas staphylocoagulase is by itself inactive under this circumstance (table 5). Because of its action on fibrinogen the new substance is designated as

coagulase-thrombin The clotting time of plasma depends on the plasma dilution and the concentration of CT If the clotting times of 1 to plasma are plotted against the concentration of CT (fig 3) a curve is obtained which is similar to figure 1 and to those obtained with thrombin and prothrombin

FIG 3—CONCENTRATION-CLOTTING TIME CURVE FOR CT A standard preparation of CT taken as 100 per cent diluted to contain 90 per cent 80 per cent etc. of CT against oxalated human plasma 1 to at 37 C.

#### DISCUSSION

Data has been presented to show that properly prepared filtrates of broth cultures of some strains of *Staphylococcus aureus* contain a substance (staphylocoagulase) which will clot oxalated plasma Staphylocoagulase is by itself incapable of clotting purified fibrinogen, but in the presence of an accessory globulin substance (coagulase globulin, CG) a second agent is formed (coagulase thrombin, CT) whose action is thrombin-like

While reluctant to introduce a new terminology we feel that the one proposed here is the most descriptive and least confusing The literature has been much confused by the application of the term staphylocoagulase or coagulase to whole cultures, filtrates, and as well, to the substance responsible for coagulating fibrinogen Smith and Hale<sup>16</sup> clearly differentiated the two substances, but their suggested terminology of procoagulase for the bacterial substance and coagulase for the agent which clots fibrinogen is based on the assumption that the first is acti-

vated by the globulin substance to form the second. Actually it seems from preliminary observations that the thrombin-like product is derived from the plasma globulin, so that it would not be accurate to call it coagulase. Further justification for our nomenclature will be presented in subsequent studies dealing with the relationship of these substances to prothrombin and thrombin.

The data indicates that CG cannot be identified with either the AcG of Seegers or the V factor of Owren. It appears to be more closely related to anti-hemophilic globulin, but is not identical with it, since CG is obtainable from hemophilic blood as contrasted to anti-hemophilic globulin which is not. The final identification and characterization of CG must await its isolation in purer form than now available, but it promises to shed some additional light on the mechanism of blood coagulation.

### SUMMARY

1. Sterile cell-free filtrates of broth cultures of some strains of staphylococci contain a substance (*staphylocoagulase*) which does not clot purified fibrinogen, but does clot oxalated plasma.

2. When a plasma factor (*coagulase globulin, CG*) is added to staphylocoagulase a thrombin-like substance (*coagulase-thrombin, CT*) is progressively formed which is able to clot purified fibrinogen.

3. When the clotting times of plasma with increasing amounts of either staphylocoagulase or CT are plotted against concentrations of the clotting agents, hyperbolic curves are obtained which are similar to those obtained with classic prothrombin or thrombin.

4. CG appears to be distinct from AcG (Seegers), the V factor of Owren, and "anti-hemophilic globulin" of Taylor and co-workers. The presence of CG in platelets could not be demonstrated.

## MULTIPLE MYELOMA AS A FORM OF LEUKEMIA

By MICHAEL A. RUBINSTEIN, M D

THE FIRST case of multiple myeloma was reported as *mollities ossium* by Dalrymple, McIntyre, Bence-Jones and Watson<sup>1</sup> in 1848, following closely the first description of leukemia as a disease entity published independently by Craigie, Bennett, and Virchow (1845).<sup>2</sup> The important pathologic studies of Rustizky (1873)<sup>3</sup> and Kahler (1899)<sup>4</sup> established multiple myeloma as a malignant infiltrative disease of the bone marrow of unknown origin, characterized by multiple tumor involvement of the skeleton. Almost at the same time Neumann's<sup>5</sup> description of the myelogenous form of leukemia (1870) and Ehrlich's discovery of blood staining methods<sup>6</sup> led to the recognition of leukemia as a primary proliferative disease of hematopoietic tissues, medullary and extramedullary. Extension of leukemic lesions from the bone marrow to the bone itself was also recorded in early observations (1878).<sup>7</sup>

Since then, as both multiple myeloma and leukemia were recognized as primary infiltrative diseases of bone marrow, their relationship has been the subject of continued discussion. Rustizky<sup>3</sup> was first to classify multiple myeloma as a systemic disease of the hematopoietic tissues related to leukemia, a view taken later by Lubarsch.<sup>8</sup> However, most authors have made a sharp distinction between multiple myeloma and leukemia. The following points have been stressed in the literature and have been conventionally held to distinguish multiple myeloma from leukemia.

### CONVENTIONAL POINTS OF DISTINCTION BETWEEN MYELOMA AND LEUKEMIA

1 *Type of infiltration* (whether circumscribed or diffuse) It has been maintained that whereas multiple myeloma produces circumscribed tumor masses, leukemia is characterized by generalized diffuse infiltration of marrow.

2 *Bone destruction* The distinction made here is that multiple myeloma is characterized by the presence of multiple punched out areas of bone destruction, while in leukemia the infiltrative process in the bone marrow does not as a rule erode the bone cortex.

3 *Visceral involvement* It has been contended that in contradistinction to the myelomatous proliferation which was held to be typically limited to the osseous system, the leukemic infiltration exceeds as a rule the boundaries of bone marrow and is found in visceral organs as well.

4 *Invasion of peripheral blood* While leukemia is manifested, at least at some stage of its evolution, by massive invasion of the peripheral blood by the leukemic cells of the bone marrow, the myeloma cells, it has been maintained, do not pass into circulation.

5 *Biochemical characteristics* Multiple myeloma is associated with abnormalities in protein metabolism manifested in Bence-Jones proteinuria and hyperprotein-

From the Medical Division, Montefiore Hospital, New York, N. Y. The material presented in this paper formed the basis for a Scientific Exhibit in the Section on Internal Medicine at the Ninety-Seventh Annual Session of the American Medical Association, Chicago, Ill., June 23-26, 1948.

emia with hyperglobulinemia. On the other hand, abnormal chemical metabolism in leukemia is manifested mainly in increased basal metabolic rate and elevated uric acid of the blood.

6 *Age incidence* It has been pointed out that while leukemia has been observed at all ages, including infancy, multiple myeloma is a disease of the middle and older age groups.

7 *Symptomatology* Bone lesions are the main basis of the clinical picture in multiple myeloma, while symptoms in leukemia are mainly due to involvement of hematopoietic and visceral organs.

Each of these points in the differential diagnosis between multiple myeloma and leukemia will be discussed. Evidence will be brought to show that the listed points of distinction between multiple myeloma and leukemia cannot be regarded as being of fundamental nature, i.e., there is no sharp demarcation line between the two diseases. Instances are abstracted where cases of multiple myeloma show the various characteristics of leukemia and vice versa.

#### FEATURES OF LEUKEMIA IN MULTIPLE MYELOMA

##### 1 *Diffuse infiltration in multiple myeloma, without circumscribed tumor formation*

It has been shown by many observers that in addition to the well known circumscribed tumor formation, diffuse infiltration of the bone marrow also exists in multiple myeloma. Such cases of diffuse infiltration without any evidence of circumscribed tumor formation are known.<sup>9</sup>

Occasionally cases of multiple myeloma have been observed where the bones appear normal. The spongy trabeculae are numerous and the cortices are not noticeably thinned. The skeletal roentgenograms taken during life in such cases may show at most some diffuse osteoporosis, and do not reveal anything even remotely suggestive of the picture which is accepted as being typical of multiple myeloma. In these cases, only the marrow is modified and replaced diffusely by a tissue which on histologic examination of aspiration material is proved to be myelomatous tissue.

Other cases show some thinning of the cortices as well as great reduction of the spongy trabeculae, but they still may have smooth and undistended bone contour. The roentgenograms show vague mottled rarefaction and thinned cortices. These cases are transitional to the full-fledged picture with multiple areas of bone destruction in typical cases of exuberant growth of myelomatous tissue.

Lack of circumscribed tumor formation does not rule out the possibility of multiple myeloma.

The case reported below is an instance of such diffuse infiltration of bone marrow without apparent evidence of bone destruction. It emphasizes the importance of bone marrow studies in any case of atypical amyloidosis, with or without evidence of bone lesions.

*Case 1* M. S. #38462, white female admitted with signs of renal insufficiency. In 1944, bone marrow aspiration repeatedly revealed from 12 to 27 per cent plasma cells. Soon Bence Jones proteinuria was also noticed.

- Blood examination showed moderate normocytic anemia and occasional plasma cells in the smear. Later a leukemoid picture developed: white blood count 25,000; myelocytes 5 per cent; nonsegmented neutrophils 55 per cent; segmented neutrophils 25 per cent; lymph 3 per cent; plasma cells 1 per cent. Terminally plasma cells increased to 20 per cent. The plasma cells in the blood were morphologically of the same type as those in the bone marrow.

The diagnosis of multiple myeloma was suggested. However, repeated *x-ray* examinations of the skeleton showed no abnormalities at any time, and the serum proteins were low (albumin 3.4 Gm per cent to 4.2 Gm per cent; globulin 1.0 Gm per cent to 2.2 Gm per cent). The Congo red test showed 45 per cent retention. The patient's course was one of rapid deterioration marked by progressive azotemia (BUN up to 150 mg per cent). She died in March 1945.

Autopsy revealed no gross lesions in the skeleton. Microscopic examination of sections of ribs, sternum, vertebrae showed marrow largely replaced by plasma cells; trabeculae thin and amyloid de-

FIG. 1. M. S. X-ray examination revealed no evidence of bone destruction. Most extensive amyloidosis was found, such as perivascular amyloid deposits in the kidney shown here.

posited in walls of the vessels. Amyloidosis was the most important extraskelatal finding. It was most generalized, involving all blood vessels, connective tissue in lungs, ovaries, kidneys, thymus, smooth muscles of most viscera, and the cardiac muscle.

The pathologic diagnosis was plasma cell myeloma, diffuse type, atypical amyloidosis.

## 2. Extraskelatal Visceral Involvement in Multiple Myeloma

Extrasosseous myelomatous infiltrations have been reported in various organs.<sup>10</sup> It is possible that in some cases what may appear to be independent extraskelatal foci might actually have been direct outgrowth of tumor from nearby bones. However, there can be no doubt that in some cases of visceral involvement the infiltrations are of extramedullary origin. Less unusual than grossly discernible foci are microscopic infiltrations in the spleen, kidneys, lungs, lymph nodes.

Autopsy performed by Dr. D. Unterman.

Up to 1936, there were 21 cases of myelomatous visceral involvement recorded in the literature (Blumenfeld). Since that time many other instances have been added. Infiltration of practically every organ in the body has been noted (lungs, heart, spleen, liver, lymph nodes, pancreas, kidneys, adrenals, tonsils, skin, etc). Extraosseous infiltrations are more commonly seen when plasma cells are also found in the blood. Of interest is a case of plasma cell involvement of the tonsils (Jackson et al.) which preceded generalized involvement of bones by many years.

In a recent report<sup>11</sup> visceral involvement in multiple myeloma is presented as a rather common finding in the disease, if carefully looked for in microscopic studies.

FIG. 2. Bone marrow aspiration in the case of M. S. showing myeloma cell infiltration (diffuse myeloma without bone destruction)

Three of our own cases showed foci of extramedullary myelomatous spread. Two instances with involvement of the tongue (R. S. #362573)<sup>1</sup> and buccal mucosa (M. K. #43608)<sup>12</sup> respectively are reported elsewhere. A third case with extensive extramedullary involvement is presented here.

**Case 2.** A. W. #105534, a 15 year old boy in 1942 gave a three year history of pain in the left hip and fracture of left thigh. X ray studies early in the disease revealed areas of bone destruction in the skull, femur and ribs. Bone marrow aspiration revealed in 1943 the presence of myeloma cells. Bence Jones proteinuria was also discovered. There was no hyperproteinemia. Moderate hypochromic anemia was found.

In the course of a few months new lesions in different bones were discovered and several palpable tumors appeared over the clavicles, sternum, ribs. There were pathological fractures of humerus and lumbar vertebrae. However, the patient's course was marked by spontaneous remissions with healing of

fractures and periods of improved anemia and general condition. Radiotherapy was applied at different sites of the skeleton. Also a course of antimony was given. Treatment was rather difficult to evaluate in view of spontaneous remissions. In 1945 patient developed inability to urinate necessitating an indwelling catheter and ascending urinary infection followed. Terminally there was profuse rectal hemorrhage.

At autopsy\* multiple myeloma was found to involve not only the skeleton but showed also two extensive extraskeletal infiltrations: (1) One tumor mass (800 Gm) involving the pelvic space so as almost

FIG. 3. A. W. multiple punched out areas of bone destruction in the skull, ribs, sternum, vertebrae, humerus, femur, pathological fracture of the hip, palpable tumor formation over a rib.

to obliterate it with compression and infiltration of nearly all pelvic organs (ureters, bladder, prostate, seminal vesicles). (2) Another extraskeletal accumulation of myeloma tissue was found to invade and partially to replace the left kidney which weighed 350 Gm (right kidney weighed 160 Gm).

Microscopically the extraskeletal infiltrations presented the same picture as the myeloma tissue seen in the skeletal lesions. This extraskeletal involvement explained the clinical course marked by renal insufficiency and recurrent pyelonephritis with urinary obstruction. The terminal hemorrhage was due to erosion of the pelvic tumor mass through the perianal structures.

\* Autopsy was performed by Dr. R. Lubliner.

FIG 4 A W Gross specimen of the tumor of left kidney

FIG 5 A W Myelomatous infiltration of kidney (low power)

### 3 *Invasion of Peripheral Blood in Multiple Myeloma*

It has been shown that not only visceral organs, but blood itself may be invaded by myeloma cells. Although massive invasion of peripheral blood, so as to produce

the picture of plasma cell leukemia, occurs rarely (except terminally), occasional myeloma cells may be found quite often (Morissette and Watkins, and others<sup>14</sup>)

In our experience, study of smears made from the white cell layer of packed blood cells facilitates the discovery of occasional myeloma cells, and thus may become an important aid in the diagnosis. We have applied this procedure in multiple myeloma as it is used when looking for occasional abnormal cells in aleukemic forms of leukemia.

The case of M. S. #38462, abstracted previously in this paper as an instance of diffuse myeloma, showed a few myeloma cells in the blood smear. This patient may be designated as aleukemic plasma cell leukemia —by analogy to the con-

FIG. 6. Section of myeloma tumor of the kidney in the case of A. W. (high power)

ventional leukemia terminology. Another case with massive invasion of the blood, one of plasma cell leukemia, will be briefly abstracted.

*Case 3.* R. S. #362573. In this 58 year old woman the disease was ushered in by a profuse rectal hemorrhage followed by back pain, weakness and soreness of the tongue. On admission there was generalized moderate lymphadenopathy and several red nodules measuring from 1 mm to 1 cm in diameter scattered over the margin of the tongue. There was severe anemia (hemoglobin 31 per cent, red blood count 1,900,000, white blood count 6,100).

Studies of the peripheral blood smear showed 5 per cent plasma cells in an otherwise normal differential count and were the first to suggest multiple myeloma. This diagnosis was confirmed by sternal marrow aspiration which revealed 65 per cent plasma cells. Also aspiration biopsy of the lesions in the tongue showed infiltration by myeloma cells and extramedullary myelomatous spread.

X-ray studies showed multiple punched-out areas in skull ribs long bones. Bence Jones proteinuria was also noticed first intermittently and later constantly. Serum albumin was 2.9 Gm. per cent, globulin 4.4 Gm. per cent.

During eight months observation there was progressive increase of white blood count with simultaneous rise of the number of plasma cells in the peripheral blood. The highest values were white blood count 26,000 with 38 per cent plasma cells 10 per cent myelocytes.

Patient died in renal failure.

#### 4 *Biochemical Characteristics of Leukemia Seen in Myeloma*

The main biochemical findings in leukemia concern the uric acid metabolism and the basal metabolic rate. The uric acid of the blood and the endogenous uric acid elimination are greatly increased in leukemia.<sup>16</sup> Also the basal metabolic rate is increased in the great majority of cases of myelogenous leukemia and in more advanced instances of lymphocytic leukemia, and less frequently in aleukemic

FIG 7 R. S. Concentration blood smear showing myeloma cells

forms of leukemia.<sup>16</sup> These changes are ascribed to the elevated protein catabolism in leukemia.<sup>17</sup>

As may be seen from various reports in the literature, increased uric acid content of blood is a rather common finding in multiple myeloma, probably as frequently seen in this disease as in leukemia.<sup>18</sup> In three of our own cases where uric acid studies were made, it was found to be 5 mg per cent, 5.5 mg per cent and 7.5 mg per cent. As in the case of leukemia, the elevated blood uric content in multiple myeloma is thought to result from the catabolism of the proliferating cells in the bone marrow.

There are also indications of increased basal metabolic rate in multiple myeloma. This appears from some references in the literature,<sup>19</sup> as well as from our own observations. Of 7 cases of multiple myeloma without complications (fever, frac

tures, etc.) in whom we studied the basal metabolic rate, in 5 instances it was found elevated from 25 per cent to 35 per cent

### 5 Age Incidence *Multiple Myeloma in Youth*

The accepted textbook view is that multiple myeloma is a disease of older age. However, review of recent literature will show isolated instances of myeloma in

FIG 8 A W PATIENT IN HIS FIFTH YEAR OF DISEASE

younger age groups, including infants.<sup>20</sup> Also, some older records of bone diseases in youth, originally reported under various descriptions—such as lymphadenia osseum described by Nothnagel<sup>21a</sup>—must be recognized as true myeloma in the light of new knowledge. Especially noteworthy are the cases of myeloma reported by Zach and by Gordon and Schneider<sup>21</sup> in children under 10 years of age.

We have observed a case of multiple myeloma in a child, aged 12 at the onset of disease, in whom the diagnosis was not considered for three years, mainly because of his age. This case (A.W., case 2) showed extensive extraosseous involvement

and has previously been abstracted in this paper as an example of visceral involvement in myeloma. Bone marrow studies were first to suggest the diagnosis of multiple myeloma. Before these studies were done, diagnoses were entertained of osteosarcoma, Schiller-Christian's disease, etc. This case, as well as those reported in the literature, prove that youth should not rule out the possibility of multiple myeloma.

#### 6 *Symptomatology Symptoms of Multiple Myeloma not Referable to Osseous System*

While in the majority of cases, the symptomatology of multiple myeloma is due to tumor involvement of bones with resulting complications (pathologic fractures, deformities, with ensuing pain and neurologic signs, etc.), in a number of patients the complaints are not referable to osseous system,<sup>22</sup> and may be similar to those ordinarily found in leukemia.

In cases of unexplained anemia and cachexia, multiple myeloma is occasionally discovered as the underlying disease. In other instances hemorrhagic manifestations constituted the presenting signs (hematemesis, melena). Epistaxis, ecchymosis, petechiae, and bleeding from gums first suggested leukemia in patients who were proven to have myeloma. Among our own patients, in one instance (A.R. #114881) the clinical picture was dominated by uncontrollable nose bleeds, in another patient (R.S. #362573) the disease was ushered in by profuse rectal hemorrhage.

In other cases, thrombosis was reported as the presenting sign, for example, when failing vision or complete blindness due to thrombosis of central artery of the retina ushered in the clinical picture of multiple myeloma. Gastro-intestinal symptoms (diarrhea, colicky attacks, nausea and vomiting) may dominate the picture. They may be due sometimes to thrombosis of mesenteric vessels. Thrombosis may be due to the increased viscosity of the blood. The latter and the tendency of red cells to clump may give rise to peripheral vascular disturbances not unlike those seen in Raynaud's disease.

Occasionally patients in chronic renal failure diagnosed as nephritis turned out to have multiple myeloma, with the clinical picture dominated by the myeloma kidney.

Very occasionally hepato-splenomegaly was observed in multiple myeloma, and very exceptionally lymphadenopathy. This extraosseous symptomatology in multiple myeloma may be seen not only in the diffuse type of myelomatous infiltrations, but also in cases with circumscribed tumor formation and bone destruction which may remain symptomless for some time. Bone marrow examination will reveal the true nature of the disease in the absence of any symptoms referable to the osseous system.

### FEATURES OF MYELOMA IN LEUKEMIA

#### 1 *Medullary Forms of Leukemia Skeletal Involvement*

Very rare cases of leukemia have been reported (Storti, Klima and Syfried, etc.) where only the bone marrow was involved.<sup>23</sup> No visceral infiltration was found.

even on thorough autopsy examination. In these cases the diagnosis could be made only on the basis of bone marrow studies. These rare forms of leukemia would correspond to the usual forms of multiple myeloma limited to the bone marrow and without visceral involvement.

Less uncommon is involvement of different bones in leukemia. It has been well known ever since Heschl<sup>1</sup> in 1847 described osteolytic lesions in leukemia patients. Bone lesions are more common in acute leukemia, especially in children in whom x-ray examination of the skeleton proved to be an aid in the diagnosis of leukemia.<sup>24</sup> The lesions may take form of tumors, destruction and absorption of bone leading to fractures, periosteal elevations and arthritis<sup>25</sup>, the latter is produced by leukemic proliferation in juxta-articular portions of the bone. Chloroma refers to localized tumors associated especially with the acute forms of leukemia.<sup>26</sup> However, the finding of bone tumors in cases of classic chronic myelogenous leukemia has also been reported.

X-ray studies have shown that in some instances leukemia may lead to generalized decalcification of the skeleton (osteomalacic forms of leukemia). However, occasionally the x-ray pictures of bone infiltration in leukemia may resemble closely those seen in multiple myeloma (Mandl and Saxle<sup>27</sup>).

As an example, the following case is of interest:

*Case 4* F. G. #112875 white female age 30 in 1946 generalized lymphadenopathy and splenomegaly were found. Biopsy of a lymph node as well as peripheral blood and bone marrow studies (90 per cent lymphocytes) were typical of chronic lymphatic leukemia. Patient developed extremely severe pain in left thigh and toes and required increasing doses of opiates. X-ray examination showed areas of translucence in the femur and also several areas of bone destruction in the distal phalanges of the foot. Relief of pain followed x-ray therapy to the affected bones.

## 2. Biochemistry of Leukemia

Bence-Jones proteinuria and hyperproteinemia, admittedly typical of multiple myeloma, have also been occasionally observed in leukemia.<sup>28</sup> These observations were made more frequently in the lymphatic than in the myeloid variety. Magnus-Levy in 1932 collected 11 cases of lymphatic and 5 cases of myeloid leukemia showing Bence-Jones proteinuria. Although only two cases have been reported of leukemia associated with hyperglobulinemia, the actual number is probably much larger, as appears from the literature on occurrence of hyperproteinemia in general. Bence-Jones proteins in the plasma have also been observed in leukemia.<sup>29</sup>

From our own observations, 2 cases of leukemia will be abstracted, where Bence-Jones proteinuria and hyperproteinemia were seen. These will be briefly abstracted. Similar instances were observed by Dr. N. Rosenthal (personal communication to the author).

### *Case 5* Bence Jones proteinuria in leukemia

The diagnosis of lymphatic leukemia in the case of R. K. (case observed on the outside and at Mount Sinai Hospital) a 72-year-old male was made in 1940. At that time generalized lymphadenopathy and hepatosplenomegaly were noticed. Blood examination showed moderate anemia. White blood count was 50,000 with 89 per cent lymphocytes of mature type. Also bone marrow (90 per cent lymphocytes) and biopsy of a lymph node were typical of lymphatic leukemia.

In March 1944 Bence Jones proteinuria was discovered. At that time the hepato-splenomegaly and lymphadenopathy had considerably increased, and white blood count rose to 250,000 with 5% of the lymphocytes. On admission to the Mount Sinai Hospital in March 1944, a rev examination of the bone showed no abnormalities and the serum proteins were normal or low.

At first Bence Jones proteinuria was found only intermittently but since November 1944 it was present constantly in large amounts. During his hospitalization repeated roentgenographic examination

FIG. 9. H. L. LYMPHATIC INFILTRATION OF BONE MARROW IN A CASE OF LEUKEMIA WITH HYPERPROTEINEMIA

were made of the skull, ribs and long bones, but no evidence of bone lesions was ever found. In spite of treatment (radiotherapy transfusions) the patient's course was progressively downhill and he died as the anemia became very severe with very high white blood count (up to 500,000) almost entirely composed of lymphocytes.

#### Case 6 Hyperproteinemia in leukemia.

H. L. #38593 65 year old white male, admitted because of weakness, frequent necklaid, hepatosplenomegaly and general lymphadenopathy. Studies of peripheral blood revealed a picture of leukemia: hemoglobin 6 Gm., red blood count 2,300,000, white blood count 50,000, lymphocytes 6%.

cent This diagnosis was confirmed by sternal marrow examination (90 per cent lymphocytes out of a total nucleated cell count 110 000), and by biopsy of a cervical lymph node

A most striking finding was very marked hyperproteinemia due to hyperglobulinemia, consistently seen on repeated examination

#### Serum protein values

Date	Alb	Glob	Englb	Psglb I	Psglb II
7 26	4 7	9 3	3 1	1 5	4 7
9 20	5 1	8 5	4 5	0 3	3 7

The formol gel test was immediately positive There was excessive rouleaux formation and a rapid sedimentation rate of red cell (80mm/hr) The urine was positive for albumin but negative for Bence Jones protein The basal metabolic rate was plus 21 per cent

X-ray examination of the skeleton failed to reveal any destructive lesion or even osteoporosis

At autopsy the diagnosis of lymphatic leukemia was confirmed

### 3 *Symptomatology of Leukemia Referable to Osseous System*

It has been mentioned in a previous chapter that bone lesions may be found in leukemia, especially in acute forms in children Sometimes symptoms referable to the bones and joints may dominate the clinical picture Pain, limitation of movement and other symptoms which suggest various bone and joint diseases (such as rheumatic fever, Still's disease, caries of the spine, osteomyelitis, etc) may occur in leukemia<sup>30</sup>

Symptoms may arise as the result of compression by bone tumors on nerves Bone tenderness is not infrequent and may be elicited usually in the lower portion of the sternum<sup>31</sup> The following case illustrated the domination of the clinical picture by bone and joint pains

*Case 7* N G #39335, boy of 18, was diagnosed in the beginning as a case of acute rheumatic fever because of migrating pains in the joints of all extremities Later the pain became more localized in the left knee which was swollen and stiff The diagnosis of osteomyelitis was then suggested

However blood and bone marrow studies revealed a picture characteristic of chronic myeloid leukemia Also splenomegaly was soon noticed Throughout the disease, pain in the bones especially in the elbows and knees remained a prominent feature X ray studies revealed generalized decalcification of long bones

### COEXISTENCE OF MULTIPLE MYELOMA AND LEUKEMIA

The literature contains a number of reports indicating the coexistence of leukemia and multiple myeloma<sup>32</sup> Apart from plasma cell leukemia, clinical multiple myeloma was found in combination with lymphatic leukemia and more rarely with myeloid leukemia

Also, experimental evidence suggests a connection between multiple myeloma and leukemia<sup>33</sup> Successive inoculations of transplantable leukemia in mice may give rise to multiple myelomatous infiltrations, instead of true leukemia (Furth)<sup>34</sup> The result obtained, whether multiple myeloma or leukemia, seemed to depend on the dosage of inoculated tissue, and on the state of the recipient animal (whether

previously irradiated or not) In connection with these observations and experiments, our case of extensive combined lymphocytic and plasma cell infiltration is of interest

*Case 8 Combined lymphocytic and plasma cell infiltration*

R. K. #372229 age 50 white female was admitted with a diagnosis of lymphatic leukemia because of marked generalized lymphadenopathy and typical blood findings hemoglobin 6 Gm per 100 cu. cm red blood count 2,000,000 per cu. mm white blood count 18,000 per cu. mm the differential count showed 80 per cent lymphocytes of the mature type 1 per cent plasma cells, 19 per cent neutrophils. Biopsy of a lymph node performed at another hospital was reported as typical of lymphatic leukemia.

At the Montefiore Hospital, bone marrow aspiration showed mixed lymphocytic (38 per cent) and plasma cell (21 per cent) infiltration. The rest of the bone marrow cells of the white and red cell series were crowded out but showed the normal myeloid-erythroid ratio. The mixed lymphocytic and plasma cell infiltration was found on both sternal and iliac bone marrow aspirates. The peripheral blood

FIG. 11. N. G. BONE MARROW IN STAGE OF ACUTE EXACERBATION OF LEUKEMIA

studies showed white blood count 20,000 lymphocytes 80 per cent, plasma cells 2 per cent. The lymphocytes in the blood and bone marrow were of the small cell type, as seen in chronic lymphocytic leukemia but the plasma cells often showing multiple nuclei with nucleoli were suggestive of myeloma cells.

There was hyperglobulinemia (albumin 2.9 mg per cent, globulin 4.1 Gm per cent) excessive rouleaux formation rapid sedimentation of red blood cells and positive formal gel test of the serum. No Bence Jones proteinuria was seen.

The possibility of multiple myeloma was suggested. However x-ray studies showed no evidence of bone destruction. The patient died four years after onset of disease. Autopsy findings were described as follows:

Malignant mixed lymphocytic and plasma cell lymphoma involving peripheral intrathoracic and intra-abdominal lymph nodes spleen and bone marrow with infiltration of most organs (liver, lungs heart stomach, kidneys, adrenals pancreas) There were both focal and diffuse infiltrations of these organs

The infiltrations, whenever seen were composed of lymphocytes and plasma cells in varying proportions in many places the latter cells being by far predominant and occurring in clumps These plasma cells were described as being identical in cytology and staining reactions (Papanheim stain, etc.) with those seen in plasma cell tumors

The pathologic diagnosis was malignant mixed lymphocytic and plasma cell lymphoma, showing both diffuse infiltration and circumscribed tumor formation

FIG. 11 R. K. HIGH POWER EXAMINATION OF LYMPH NODE SHOWED PREDOMINANTLY PLASMA CELL INFILTRATION Low power examination showed destruction of gland architecture by plasma cell infiltration

#### DISCUSSION

The conventional points in differential diagnosis between myeloma and leukemia have been discussed The following points have been held to distinguish the two diseases (1) Type of infiltration, whether diffuse or circumscribed (2) Bone destruction (3) Extraskelatal visceral involvement (4) Invasion of peripheral blood (5) Biochemical characteristics (6) Age incidence, clinical manifestations

It has been shown, by assembling different data from the literature and on the basis of our own observations, that the difference between myeloma and leukemia, as far as these characteristics are concerned, is merely one of incidence, what is rare in one disease is common in the other Instances of myeloma may show all the characteristics of leukemia, and vice versa, but not with the same frequency

The following table summarizes the discussion

Points in differential diagnosis	Leukemia	Myeloma
Circumscribed tumors	Uncommon	Common
Bone destruction	Uncommon	Common
Visceral involvement	Common	Uncommon
Peripheral blood invasion	Common	Uncommon
Hyperproteinemia	Uncommon	Common
Bence Jones proteinuria	Uncommon	Common
Bone symptoms	Uncommon	Common
Incidence in youth	Common	Uncommon

It is known that there is a difference in incidence of various leukemic characteristics depending upon the cell type of leukemia (myelogenous, lymphatic, etc. Certain features (such as splenomegaly, lymphadenopathy, skin or skeletal involvement etc.) are more common in one variety than in the other. All the features of leukemia may be found in all leukemic varieties, but not with the same frequency. It has been demonstrated in our discussion that myeloma may show all the characteristics of leukemia, and vice versa, but not with the same frequency. This is however merely a quantitative difference. As far as the listed characteristics are concerned, there is no qualitative difference between myeloma and leukemia.

*Myeloma is, then merely a leukemia of plasma cells.* This variety of leukemia is ordinarily of aleukemic type. Moreover, as compared to other leukemias, it is characterized by very common occurrence of bone destruction, by relatively infrequent visceral involvement, and by frequent and characteristic biochemical abnormalities in protein metabolism. It has a definite predilection for older age groups and its clinical picture is usually dominated by bone pathology. In this light viewing myeloma as another member of the leukemia family, it is more plausible to understand the coexistence of myeloma and leukemia as something more than accidental.

#### SUMMARY

The conventional points in the differential diagnosis between myeloma and leukemia have been discussed. Evidence has been brought to show that these points of distinction cannot be regarded as being of fundamental nature. Instances are abstracted where cases of multiple myeloma show the various characteristics of leukemia and vice versa.

1. *Leukemic features in myeloma have been shown in*
  - a. diffuse infiltration in multiple myeloma without circumscribed tumor formation and without any gross bone destruction,
  - b. extraskelatal visceral myelomatous spread involving the kidney, spleen lymph nodes, etc
  - c. invasion of peripheral blood in myeloma—occasional myeloma cells (corresponding to the aleukemic forms of leukemia) may frequently be found in concen-

trated smears, even though they may be missed on routine examination, however, massive invasion of peripheral blood is rare,

d increased uric acid content of the blood and elevated basal metabolism, characteristic of leukemia, frequently seen also in myeloma,

e occurrence of myeloma in youth,

f symptomatology of multiple myeloma at times not referable to the osseous system

2 *Myeloma features in leukemia have been shown in*

a skeletal involvement in leukemia,

b very rare medullary forms of leukemia (without visceral involvement),

c occurrence of Bence-Jones proteinuria or

d hyperproteinemia with hyperglobulinemia in rare cases of leukemia,

e instances when the symptomatology of leukemia was referable to the osseous system

3 *Coexistence of multiple myeloma and leukemia* is reviewed from the literature, and a case is reported of extensive mixed lymphocytic and plasma cell infiltration

In conclusion, the difference between myeloma and leukemia, as far as the listed conventional distinguishing features are concerned, is merely one of incidence what is rare in one disease, is common in the other, and vice versa Multiple myeloma is in all probability a leukemia of plasma cells

## USE OF ANTIMONY IN MULTIPLE MYELOMA

By MICHAEL A. RUBINSTEIN, M.D.

IN A previous communication<sup>1</sup> the rationale of antimony treatment in multiple myeloma was discussed, and a preliminary report was given on the results obtained. Because the therapeutic effect of antimony is largely confined to diseases associated with hyperglobulinemia regardless of the etiologic factor involved (kala-azar, lymphogranuloma venereum, schistosomiasis, etc.), it was assumed that the drug might be found effective in another disease with hyperglobulinemia namely, in multiple myeloma. The effects of antimony as originally reported were to induce increased radiosensitivity, and to result in certain alterations in the morphology of the plasma cells.

The present paper, based on a total of 11 cases, treated with antimony, reports some new observations in addition to those mentioned in the first communication. These observations concern the effect of antimony treatment seen in (1) stoppage of uncontrollable bleeding, (2) reduction of hyperglobulinemia, (3) regression of palpable tumors. The dosage and the preparations used were the same as those previously described.<sup>1</sup>

### 1. Relief of Uncontrollable Bleeding

The patient A. R., #114881, was a 64 year old male. In July 1945 he developed recurrent severe nosebleeds and soon afterward started to complain of backache. The nosebleeds were stopped at that time by cauterization. In January, November and December 1946 and early in 1947 there was a recurrence of epistaxis controlled by packing. In April 1947 the nosebleeds became almost continuous and uncontrollable by either packing or cauterization and patient had to be hospitalized.

Sternal bone marrow aspiration in May 1947 revealed a picture of plasma cell multiple myeloma. Because of uncontrollable nosebleeds frequent blood transfusions were necessary.

On admission to Montefiore Hospital in January 1948 the patient was bleeding profusely from both nares but no specific bleeding points could be seen. There was gibbus deformity in the mid-thoracic area and pain with rootlike distribution over D-7. The liver was enlarged four fingerbreadths below the right costal margin.

There was severe anemia (hemoglobin 42 per cent, red blood cells 2,000,000) the white blood cell count was 5,000 with a normal differential picture. The platelet count was normal (260,000) as was the clotting and bleeding time. The only abnormality indicative of a hemorrhagic tendency was the failure of the clot to retract after forty-eight hours.

Sternal and iliac bone marrow examination showed about 70 per cent plasma like myeloma cells.

The total serum protein was 12.3 Gm, albumin 1.1 Gm, globulin 11.2 Gm, the blood urea nitrogen was 22.1 mg. per cent.

X-ray examination revealed numerous well circumscribed osteolytic areas in the vault of the skull, in the upper ends of both femurs, in the clavicles and a destructive lesion of D-9 with partial collapse of the vertebral body.

When in spite of repeated cauterizations, packing and transfusions, the nosebleeds continued to be

---

profuse radium therapy to the nasal mucosa was applied. Small catheters containing radium were inserted alternately in both nares on January 16 and 20, 1948. However, no improvement in the bleeding tendency was noted.

A course of antimony treatment was begun on February 23 and completed on March 17, 1948. Fifteen Gm. of neostibosan were given intravenously divided in 48 doses. Progressive diminution of bleeding

The case histories of D. C. and A. L. are to be found in the first communication<sup>1</sup> and those of A. R. and E. E. in this paper.

was observed in March 1948 followed by complete cessation at the beginning of April 1948. Except for a single episode of nosebleed on June 25, 1948 and occasional oozing in August 1948, there was no recurrence of bleeding to October 1948 (time of writing). Both episodes of bleeding were promptly controlled by a repeated course of neostibosan.

Since the beginning of April 1948 no nasal packing has been necessary and the patient was discharged in October 1948.

Blood examination revealed reduction of hyperglobulinemia (table 1).

## 2. Reduction of Hyperglobulinemia

In reviewing the serum protein data of all patients treated, it was found that in all 4 cases with marked hyperglobulinemia there was some reduction of the latter following antimony treatment.

A slow rise of serum globulin was observed a few weeks after discontinuance of treatments. However, it dropped again following repeated courses of treatment.

There were no significant changes in serum protein in three cases without hyperglobulinemia. In four cases the serum proteins were not followed during treatment.

## 3. Regression of Palpable Tumors

Disappearance of palpable tumors following antimony treatment was observed in all three cases showing such lesions.

Two cases were previously reported.<sup>1</sup> In one of them (A. W. #105534) rapid disappearance of external bone tumors could not be attributed with certainty to the drug, since spontaneous regression was observed in this patient. The results obtained in the second case (D. C. #110504) were more conclusive. Two tumor masses had been noticed by the patient two years prior to admission and were progressively increasing in size, in spite of x-ray treatment. At the completion of neostibosan injections, and before further x-ray treatment, the visible tumors were found to be greatly reduced and became hardly noticeable. They completely disappeared soon after the subsequent x-ray therapy.

A third case since observed will now be described, where rapid and complete disappearance of multiple palpable tumors followed antimony treatment without any local x-ray treatment.

M. K. #43608, a 61 year old female, admitted on 10.2.1947, gave a history of pain in the back of 6 months duration. Several masses on the forehead were noticed five months prior to admission and they were progressively increasing in size.

On examination four palpable masses were found over the scalp: a midfrontal mass measuring 4 cm. x 3 cm. x 2 cm., a latero-frontal 3½ cm. x 3 cm. x 1½ cm., a fronto-temporal 3 cm. x 3 cm. x 2 cm. and a parietal mass 4½ cm. x 3 cm. x 3 cm. These masses were fixed to the underlying tissues, not movable, nontender.

X-ray examination revealed numerous areas of destruction in the entire cranium as well as in the mandible, humerus, scapula, clavicles and ribs. Blood studies showed severe anemia (hemoglobin 7.7 Gm./100 cu. cm., red blood cells 1,920,000), white blood cells 15,000 with normal differential count. Blood urea nitrogen was 61 Gm. per cent, total serum protein 8.2 Gm. per cent, albumin 3.5 Gm., globulin 4.7 Gm.

Sternal and iliac bone marrow aspirations revealed clumps of myeloma cells. The diagnosis of multiple myeloma was confirmed by the presence of Bence Jones proteinuria. Aspiration of the visible masses on the forehead showed myelomatous infiltration.

A course of neostibosan treatment was started on 10.11.47. Practically complete disappearance of all four visible tumors was noticed after two weeks.

However, the patient's course was progressively downhill with increasing azotemia. Because of the severe backpain, x-ray therapy was applied to the lower spine, but at no time was radiotherapy given to the frontal tumor masses.

Patient died in uremia (blood urea nitrogen rose terminally to 186 mg. per cent) on 12.5.47.

Autopsy findings showed multiple myeloma of the skeleton with extension of myeloma tissue from the cranium to the scalp and cerebral dura. The kidneys presented the picture of myeloma nephrosis.

When recently yet another case of multiple myeloma (E. E. #457079) with large frontal palpable masses was treated with neostibosan, no regression of the

masses was obtained. A biopsy was performed and showed that these masses consisted not of myelomatous tissue but of amorphous (amyloid?) mass. At the time

FIG. 1. VISIBLE TUMOR MASSES IN THE SKULL BEFORE TREATMENT

FIG. 2. DISAPPEARANCE OF THE VISIBLE TUMOR MASSES TWO WEEKS AFTER A COURSE OF NEOSTIBOSAN INJECTIONS

when treatment was started in this 52 year old patient he was completely immobilized in bed because of multiple pathologic fractures and most extensive involvement of the skeleton. There was no noticeable effect of the single course of

treatment on the clinical course, but a reduction of hyperglobulinemia was noticed (table 1)

### COMMENT AND SUMMARY

The effect of antimony treatment (neostibosan) of multiple myeloma is described. The following observations are reported

1 *Control of bleeding* In one instance of multiple myeloma the presenting symptom was uncontrollable nosebleed of one and one-half years' duration. The platelet count as well as the clotting and bleeding time were normal, the only abnormality was the failure of the clot to retract. It is possible that the latter abnormality was connected with the abnormal protein composition of the blood (hyperglobulinemia was found).\*

Topical treatment, including repeated cauterizations and radium application to the nasal mucosa, remained without any effect, and constant packing and frequent transfusions were necessary. Following a course of neostibosan injections there was gradual diminution of the bleeding, and after one month complete cessation of bleeding was noted. Since that time (6 months at the time of writing) the bleeding did not recur, and the patient was discharged from the hospital. At the same time a moderate decrease of hyperglobulinemia was observed.

2 *Reduction of hyperglobulinemia* In reviewing all other cases treated it was found that in all four instances with hyperglobulinemia there was reduction of the serum globulin content. When a few months later the hyperglobulinemia was rising, a repeated course of antimony was followed again by its reduction.

In three instances without hyperglobulinemia no change of serum globulin was noted following the antimony treatment. In four other cases the globulin changes were not followed.

3 *Regression of palpable tumors* Three instances with visible tumors, a rather uncommon phenomenon in multiple myeloma, were observed.

Disappearance of the palpable tumors in two patients after combined antimony and radiotherapy was reported in a previous communication. In the present paper, almost complete disappearance of palpable tumors following antimony treatment alone without radiotherapy is reported.

With regard to these observations, the following reservations should be kept in mind

1 In evaluating the influence of antimony on multiple myeloma it is necessary to realize the possibility of occasional spontaneous remissions in this disease, as well as of a prolonged course over a period of years with relative freedom from symptoms, and occasional sensitivity to radiation.

2 The number of observations is insufficient to warrant at this point conclusions as to the *therapeutic value* of antimony. They indicate merely a possible influence of antimony on the myeloma tissue and on the disturbed chemistry of myeloma.

## LEUKEMIA AND MALIGNANT LYMPHOMA

**LEUKEMIA IN CHILDHOOD. A CLINICAL AND ROENTGENOGRAPHIC STUDY OF SEVENTY-TWO CASES.** *J. H. Dale, Jr.* From the New York Hospital and the Departments of Pediatrics and Radiology, Cornell University Medical College, New York, N.Y. *J. Pediatr.* 34: 421-432, 1949.

The clinical and roentgenologic findings in 72 children with leukemia have been analyzed. X-ray evidence of bone involvement was obtained in over 70 per cent of cases studied, by far the most common abnormality being the appearance of a transverse band of diminished density in the metaphyses of the long bones. This band was the first sign of skeletal disease in the majority of patients and the sole osseous change in almost half of the cases exhibiting x-ray changes. Roentgenographic signs when present invariably included evidence of involvement in the knee area, in view of which it is suggested that routine roentgen examination of this region might provide a helpful screening technique in the investigation of all suspected cases of leukemia, perhaps obviating the necessity of more extensive skeletal surveys.

**CHRONIC LEUKEMIA OF LONG DURATION. A REPORT OF 31 CASES WITH A DURATION OF OVER 5 YEARS.** *H. C. Moffitt, Jr. and J. H. Lawrence.* From the Divisions of Medical Physics and Medicine, University of California, Berkeley, Calif. *Ann. Int. Med.* 30: 778-790, 1949.

The life duration of patients with chronic leukemia is summarized from the literature by the authors. The frequency of remission, effect of infection and treatment is discussed. The hematologic data of 31 patients with lymphogenous and myelocytic leukemia chosen from 190 cases of the authors because of their long survival are tabulated.

C. A. F.

**OBSERVATIONS IN GUINEA PIGS FOLLOWING INJECTION OF SPECIFIC HEMATOPOIETIC SUBSTANCES DERIVED FROM BEEF LIVER.** *L. M. Meyer and A. Sawitsky.* From the Department of Therapeutics, New York University College of Medicine, New York, N.Y. *Am. J. Path.* 24: 835-855, 1948.

The authors report pathologic changes observed in guinea pigs receiving repeated intramuscular injections of extracts prepared from normal beef liver as follows:

An ethanol extract of dried liver, after concentration and saponification, was repeatedly extracted with ether before and after treatment with carbon dioxide and hydrochloric acid. After successive extractions with petroleum ether and methanol, the material was treated with lead and the acidified ether-insoluble lead salts were crystallized at minus 20 degrees C. in acetone. The noncrystalline material in the mother liquor having been concentrated (B-acids), it was separated by succination into carbinols and noncarbinols.

Nine animals received B-acid extracts derived from 200-800 grams of beef liver. Seven of this series

developed Hodgkin's like lesions in cervical nodes, spleen, liver, adrenal and kidney. The bone marrow exhibited myeloid hyperplasia in 6, lymphoid hyperplasia in 1 and no changes in 2 animals. Myeloid metaplasia of the cervical nodes and spleen were noted in 1 guinea pig. The carbinol fraction was injected into 12 guinea pigs, in 9 of which a lymphoid reaction developed, myeloid changes being noted in another of this series. Of 18 guinea pigs receiving the noncarbinol fraction, 13 exhibited varying grades of myeloid reaction, 5 others presenting evidence of a mixed myeloid and lymphoid stimulation, definite myeloid hyperplasia resulted in 13 animals of this series.

It is concluded that beef liver extracts of the carbinol type stimulated lymphoid hyperplasia and infiltration and those of the noncarbinol type myeloid hyperplasia and infiltration when injected into guinea pigs. The resultant lesions were clinically and pathologically dissimilar to spontaneous leukemia. A reciprocal relationship between myeloid and lymphoid tissues with respect to their reactivity to hemopoietic stimulation and relative rates of proliferation appears to have been confirmed.

C. P. E.

**OBSERVATIONS IN GUINEA PIGS FOLLOWING INJECTION OF SPECIFIC HEMATOPOIETIC SUBSTANCES DERIVED FROM URINES OF HUMAN LEUKEMIC SUBJECTS.** *A. Sawitsky and L. M. Meyer*. From the Department of Therapeutics, New York University College of Medicine, New York. *N. Y. Am. J. Path.* 44: 1117-1137, 1948.

Guinea pigs were injected with urine extracts including the carbinol fractions of urines from patients with lymphoid leukemia, and noncarbinol fractions derived from the urine of patients with myeloid leukemia. Although the resultant lesions were clinically and pathologically dissimilar to those characteristic of spontaneous leukemia, the results suggested that the urines of leukemic patients contain materials which are extractable and separable by the methods described. Carbinol fractions inducing a specific lymphoid hyperplasia and infiltration, and the noncarbinol fractions inducing a myeloid response.

C. P. E.

**HODGKIN'S DISEASE. A CLINICAL-PATHOLOGICAL REVIEW OF ONE HUNDRED FIFTY CASES.** *W. L. Bessell*. From the Department of Pathology, University of California Medical School, San Francisco, Calif. *California Med.* 70: 87-92, 1949.

In 150 cases of Hodgkin's disease studied during the last twenty-five years at the University of California Hospital, the average survival period was forty-one months. Individuals whose lesions histologically were paraneoplasia had no longer survival periods than those with the classic granuloma. The authors emphasize that non-Hodgkin's disease tumors are more likely to be included as Hodgkin's sarcoma or as paraneoplasia than they are to be confused with the granulomatous form. In this series, the tuberculin test was negative in a high percentage of individuals studied. The incidence of tuberculosis associated with the Hodgkin's was only slightly higher than in the general autopsy group. Bacteriologic studies were unproductive except that fertile egg passage of cell-free lymph node filtrates resulted in increased egg mortality and increased cutaneous sensitivity reactions to the harvested amniotic fluid.

W. N. V.

**HODGKIN'S DISEASE. A HISTOPATHOLOGICAL AND CLINICAL CLASSIFICATION WITH RADIOTHERAPEUTIC RESPONSE.** *P. F. Salyers and S. J. Eisenberg*. From the Departments of Surgery and Radiology, Medical College of Virginia, Richmond, Va. *Am. J. Roentgenol.* 61: 369-379, 1949.

Hodgkin's disease is classified into (1) compact cellular, (2) fibrogranulomatous and (3) loosely cellular types. The compact cellular type was characterized by closely packed lymphocytes, some reticulo-endothelial proliferation with Sternberg-Reed cells. The fibrogranulomatous type was that of typical Hodgkin's granuloma. The loosely cellular type showed complete loss of structure of the lymph nodes with sheets of reticulo-endothelial cells and frequent mitotic figures. The report is concerned with an attempt to prognosticate from the histologic picture of 24 patients the clinical course of the disease. The compact cellular type had a life expectancy of 48 to 160 months, the fibrogranulomatous 20 to 60 months and the loosely cellular 12 to 20 months.

The prognostic implication of these studies would seem rather similar to the more extensive studies

of Parker and Jackson. It is unfortunate that some differences in classification make it impossible to compare the different groups of patients.

C A F

**SKELETAL LESIONS IN HODGKIN'S DISEASE.** *E. H. Falconer and M. E. Leonard.* Department of Medicine, University of California Medical School, San Francisco, Calif. *Ann Int Med* 29: 1115-1131, 1948.

In summarizing their own and other reported material on skeletal lesions of Hodgkin's disease, the authors stress the underlying marrow involvement. They have studied by sternal aspiration 59 patients with proven Hodgkin's disease and reviewed pathologic material on 20 patients looking for marrow involvement. One is impressed by the nonspecificity of changes in differential cell counts of the marrow which include (1) a shift to the left in neutrophil series with a relative decrease in segmented neutrophils and an increase in bandforms, (2) increase in eosinophilic myelocytes. There also appeared to be increased megakaryocytes in several instances. It would have been interesting to determine how frequently a specific diagnosis could have been made on aspirated pieces of marrow prepared by fixation and sectioning. In this respect, the authors indicate only that 10 of 11 of 20 autopsied cases of Hodgkin's disease was found in the marrow sections reviewed. The difficulty of morphologic differentiation between reticulo-endothelial cells, Sternberg-Reed cells and megakaryocytes is not discussed.

C A F

**DIAGNOSIS OF PRIMARY HODGKIN'S DISEASE OF THE STOMACH.** *E. L. Parker and S. M. Roberts.* From the Department of Radiology, University of Louisville School of Medicine, Louisville, Ky. *Radiology* 52: 75-78, 1949.

To the 22 cases of primary Hodgkin's disease already in the literature, the authors add one of their own. Interest in this diagnosis stems from the fact that so far as published reports go, if the patient survives the operation of gastrectomy, complete cure is likely. The usual preoperative diagnosis, based on x-rays, is extensive infiltrating carcinoma of the stomach. The authors suggest, however, that the characteristic of Hodgkin's disease is polyp-like masses along the involved gastric area on the x-ray, an appearance which is relatively constant in all these cases, although there may be no other symptoms or signs or laboratory findings to suggest Hodgkin's disease.

Although the authors' patient did not survive postoperatively, autopsy failed to reveal Hodgkin's disease anywhere except in the operative specimen. The authors' data suggest that a radiographic diagnosis of extensive carcinoma of the stomach, in the absence of metastases, should not preclude attempt at operative treatment, since the diagnosis may be wrong and apparently removal of a stomach involved by primary Hodgkin's disease may result in cure.

S E

**PREGNANCY AND HODGKIN'S DISEASE—WITH A REPORT OF THREE CASES.** *S. C. Kardon.* From the Tumor Clinic and the Gynecological Department, Boston Dispensary, New England Medical Center, Boston, Mass. *Am J Obst & Gynec* 57: 282-293, 1949.

From an analysis of the literature relative to pregnancy in the course of Hodgkin's disease, 3 cases of which are described in detail by the author, it is concluded that this disease has no demonstrable influence on ovulation, fertility, or the obstetric aspects of gestation, parturition, or the puerperium. The disease was transmitted from the mother to the fetus across the placenta in 9 per cent of reported cases. No evidence was obtained to indicate that x-ray therapy results in injury to the shielded fetus. Artificial interruption of pregnancy, on the basis of coexisting Hodgkin's disease, appears therefore to be unwarranted.

C P E.

**CHEMOTHERAPY OF MALIGNANT DISEASE.** *A. Gellhorn and L. O. Jones.* From the Departments of Cancer Research and Medicine, College of Physicians and Surgeons, Columbia University, New York, N. Y. *Am J Med* 6: 188-231, 1949.

The chemotherapeutic value of microbial products, antitumor cytotoxic serum, folic acid conjugates and antagonists, stilbamidine, urethane, androgens, estrogens, and nitrogen mus-

rards is comprehensively and critically reviewed from the standpoint of investigative efforts and rationale leading to their clinical use, mechanism of action and clinical application and limitations, 186 references are included

The authors have drawn the following conclusions (1) androgen therapy is warranted in prostatic malignancy no longer localized, (2) urethane is of value in chronic myelogenous and lymphatic leukemia when x ray therapy cannot be used, (3) nitrogen mustards are useful adjuncts to radiotherapy in malignant lymphomas (4) after conventional therapy has failed, androgens in carcinoma of the breast with skeletal metastases and stilbamidine in multiple myeloma with intractable pain should be tried (5) antitreticular cytotoxic serum and teropterin have no proven beneficial effect on malignant disease, (6) estrogen treatment of carcinoma of the breast with soft tissue metastases in postmenopausal women needs further investigation and (7) microbial products to date have not proved effective in the treatment of human neoplasms

The concept that our failure to produce cures may be due to the fact that certain cells in a neoplasm behave like bacteria which are capable of developing resistant strains to chemotherapeutic agents, is interesting. From that point of view one wonders if the simultaneous administration of several potent chemotherapeutic agents early might not offer even greater therapeutic benefits than alternate therapeutic courses over a longer period of time

H B M

CHEMOTHERAPY OF LYMPHOMA AND LEUKEMIA *W Dameshek* From Tufts College Medical School and the Pratt Diagnostic Hospital Boston Mass Bull New England M Center 11 49-62, 1949

This paper presents a concise historical review of chemotherapy in the proliferative disorders of the white cells and summarizes the author's experiences with nitrogen mustard (described in Blood 4 335 1949) and with certain folic acid antagonists, including aminopterin, a methopterin, amino-20-fol and a binopterin. Of 21 cases of acute or subacute leukemia who survived more than four days after initial therapy, remissions occurred in 9. The most pronounced drug toxicity and greatest efficacy were demonstrable in the patients receiving aminopterin which proved to be as effective and toxic when administered orally as when given parenterally. It was apparently necessary to produce definite toxic manifestations in order to achieve a remission. Therapeutic complications included ulceration of tongue and mucous membranes, nausea, upper abdominal discomfort and diarrhea. Vascular purpura and an enhanced bleeding tendency were also observed.

It was concluded that the folic acid antagonists possess, in varying degrees, the capacity to induce remissions in about one third of the cases of acute and subacute leukemia both in adults and in children and in both leukemic and leukopenic forms. Clinical hematologic and at least partial marrow remissions occurred most commonly in lymphocytic and least often in monocytic leukemia. Although by no means curative, these agents were therapeutically effective to a degree suggesting that with increasing knowledge of cellular enzyme systems and their inhibitors, great improvement in the treatment of leukemia may be anticipated and that the successful control of this disease may ultimately be achieved.

C. P. E.

EFFECTS OF FOLIC ACID ANTAGONISTS INOCULATED IN EMBRYONATED EGGS *P F Wagley and H R Morgan* From the Thorndike Memorial Laboratory Boston City Hospital Boston Mass Arch Path 44 441-450 1948

Since 1928 when Sabin first reported that fraction R of liver extract would influence the development of primitive erythroblasts of living chick blastoderms, contradictory results have been obtained by various investigators. Muller (1930) and Hays, Last and Koch (1942) obtained negative results. Reimer (1938) observed nonspecific degenerative changes in the liver. More recently, Riggio (1942) has observed that chick embryos incubated 32-33 hours responded to liver extract in three ways: viz. reversal of the ratio of erythroblasts and micromegakaryoblasts, reduction in percentage of histioid cells and an increase of mitoses in prophase. The present article by Wagley and Morgan is important because it shows that when some folic acid antagonists are injected into the yolk sac of chicks incubated for six to eight days, hemopoiesis is definitely influenced. Blood islets are decreased in size and number, nuclei exhibit pyknotic karyolysis and karyorrhexis. The larger doses of antagonists shortened the time for survival of the embryos. It was possible to protect against this effect by using relatively large doses of folic acid but not

possible with the dosage of liver extract and vitamin B<sub>12</sub> used. In this connection it should be noted that Rusznayk, Löwinger and Lajtha (1947) reported that folic acid acts directly on megaloblasts in tissue culture. Methyl 4 aminopteroylglutamic acid was not as potent as 4 amino-pteroylglutamic acid and N<sup>10</sup> methylpterotic acid had no effect in relatively large doses. Experiments like this should be encouraged and extended.

O P J

THE BLOOD CELLS AND THE HEMOPOIETIC AND OTHER ORGANS OF DOGS GIVEN INTRAVENOUS INJECTIONS OF 2-CHLOROETHYL VESICANTS. *J E Kinsler*. From the Anatomical Laboratory, University of Virginia, Charlottesville, Va. Arch. Path. 47: 378-399, 1949.

The present experiments reinvestigate on dogs experiments of a similar nature previously conducted on rats. Although the data are of a similar nature, better information concerning the daily changes in the blood picture were obtained. The material consisted of 17 dogs and the vesicants used were bis (2-chloroethyl) sulfide dissolved in thiodiglycol, the hydrochlorides of ethyl bis (2-chloroethyl) amine and tris (2-chloroethyl) amine dissolved in isotonic sodium chloride solution just before being injected into the saphenous vein. The results indicate that not only are vesicants rapidly acting specific poisons, but that they have a slower, more general intoxicating effect. Secondary pathologic changes occur in the organs which are believed to interfere with their proper functioning.

O P J

MULTIPLE MYELOMA. ITS CLINICAL AND LABORATORY DIAGNOSIS WITH EMPHASIS ON ELECTROPHORETIC ABNORMALITIES. *W S Adams, E L Alling and J S Lawrence*. From the Departments of Medicine and Radiology, University of Rochester School of Medicine and Dentistry, and the Medical Clinics of the Strong Memorial Hospital and the Rochester Municipal Hospital, Rochester, N. Y. Am. J. Med. 6: 141-161, 1949.

Sixty-one cases of multiple myeloma were analyzed and emphasis was placed on the most common and characteristic clinical and laboratory findings. A large section of this presentation is devoted to the electrophoretic study of the plasma protein abnormalities. These studies were considered of particular value in the differential diagnosis of this disease.

Of the 30 cases of multiple myeloma studied electrophoretically, 21 showed major abnormal patterns with tall, narrow peaks; 8, without such peaks, presented slight but significantly irregular pattern abnormalities; and 1 case of solitary myeloma of the autum with chronic infection showed patterns consistent only with infection.

The association of Bence Jones protein with multiple myeloma is discussed. It was observed that the incidence of Bence Jones proteinuria was low in the group with large abnormal peaks in their electrophoretic patterns but high in those patients with only small abnormalities. It is suggested that these small abnormal peaks were due to Bence Jones protein in the plasma and the Bence Jones proteinuria occurred in these patients because of the absence in the plasma of a protein of high molecular weight capable of forming complexes with Bence Jones protein.

Undoubtedly, electrophoretic studies will prove of great value in the future in our objective evaluation of the beneficial effects in this disease of the various chemotherapeutic agents.

H B M

## RADIATION EFFECTS

ABERRANT TISSUE DEVELOPMENTS IN RATS EXPOSED TO BETA RAYS. THE LATE EFFECTS OF P<sup>32</sup> BETA RAYS. *P S Hinshaw, R S Snider and E F Riley*. From the Clinton National Laboratory, Biology Division, Oak Ridge, Tenn. Radiology, 52: 401-415, 1949.

The exposure of rats to large single or repeated doses of beta rays from P<sup>32</sup> externally placed resulted in the appearance in the rats, some ten to twelve months later, of a large variety of tumors of the skin and subcutaneous connective tissue. Rats were exposed either to single doses of beta irradiation from plastic materials containing radioactive phosphorus or to repeated daily doses for a period of months. If the dose was sufficiently low, there were no effects of the irradiation. When single doses of 4,000 to 6,000 rep (roentgen equivalent physical) were given, typical changes occurred as follows. In one week,

acute skin erythema was followed by desquamation alopecia ulcers and in some rats death in four weeks Rats which survived showed healing of ulcers blindness, falling off of the ears alopecia telangiectasia of the skin and ultimately, neoplasms The neoplasms were of all varieties seen in the skin and connective tissue and were malignant Certain nonmalignant changes (production of extra claws soft tissue papillomata) also occurred

These changes were less marked at single doses of 8 000 rep suggesting an optimal range for their production They were much less marked in certain of the animals exposed to small daily doses over a period of months Tumors did not occur in control males and were much less frequent in control females

No conclusions are drawn which might relate to human usage of internal beta irradiation (i.e. in clinical application of  $P^{32}$  therapy) The range of dosage in the authors' experiments was extremely large (1 rep is the amount of ionizing radiation produced in one gram of tissue by 1 roentgen) and outside the clinical range The conclusion however that this type of irradiation resulted in a change in the destiny of certain cells is obviously tenable and of great interest in questions of growth

S. E.

## BONE MARROW

**NORMAL AND PATHOLOGIC PHYSIOLOGY OF THE BONE MARROW** *W. W. Zuelzer* From the Anemia Clinic of the Children's Hospital of Michigan and the Department of Pediatrics Wayne University College of Medicine Detroit Michigan *Am J Dis Child* 77 482-502, 1949

Several interesting and logical, although admittedly controversial, concepts are presented in this excellent discussion of normal bone marrow physiology and the functional disturbances associated with various disease states

Normal hemopoiesis involves three distinct functions (1) multiplication of precursor cells by mitosis, (2) maturation of cells and (3) release of mature elements Mitosis and maturation are considered as opposing although finely integrated tendencies in the development of the marrow cells While both processes normally occur in nearly all stages of cellular development mitosis predominates in younger cells and maturation in the more highly developed cells with a fairly even balance between the two in the intermediate stages In various pathologic states the functions of multiplication and maturation become dissociated Thus if mitotic function is lost in the more highly differentiated cells the number of immature cells increases markedly due to the depletion of the more mature cells and to the predominance of mitosis over maturation at primitive levels Maturation of such cells is therefore scanty slow and abnormal

Perhaps the most controversial point in the discussion is the concept that all immature red and white cells which appear in the peripheral blood in abnormal conditions (e.g. leukemia) come from extra medullary foci of hematopoiesis rather than from the bone marrow Several observations are cited to support this viewpoint In certain conditions in which extramedullary hematopoiesis can be demonstrated or assumed this is easily conceivable but there would appear to be noteworthy exceptions The answer must await a more thorough understanding of the mechanism of release of cellular elements from the bone marrow

H. W. B.

**STUDY OF FIXED TISSUE SECTIONS OF STERNAL BONE MARROW OBTAINED BY NEEDLE ASPIRATION III METASTATIC CARCINOMA IN STERNAL BONE MARROW** *A. S. Weissberger and R. W. Herold* From the Department of Medicine Lakeside Hospital and the School of Medicine Western Reserve University Cleveland Ohio *Am J M Sc* 217 263-268 1949

Of 50 selected patients with malignant tumors 7 were found to have metastatic lesions in the sternal bone marrow as demonstrated in tissue sections of particles obtained by needle biopsy Sternal marrow metastases were found only in the case of those tumors which have a tendency to metastasize to bone Metastatic lesions were found in the marrow in 2 patients after operations for carcinoma of the lung and breast respectively In one patient a metastatic lesion in the marrow was the only positive anterior roentgen evidence of carcinoma This would indicate that the procedure might be of benefit preoperatively in cases of carcinoma which are likely to metastasize to bone, and as a diagnostic tool in selected cases

G. E. C.

## ANEMIA

THE CLINICAL AND ROENTGEN MANIFESTATIONS OF ERYTHROBLASTOSIS FETALIS *M. Ritvo, I. A. Shaffer, and G. Kresnick* From the Departments of Radiology and Obstetrics Boston City Hospital, Boston Mass. *Am J Roentgenol* 61: 291-301 1949

Prepartum fetal roentenographic findings in erythroblastosis are described in 4 cases. These changes include increased bone density, zones of decreased density in the long bones at the cartilaginous junction, soft tissue edema, evidence of fetal death.

It would be desirable to have information on a much larger number of cases before any possible value of these changes in anticipating erythroblastosis can be evaluated.

C A F

FOLIC ACID IN COELIAC DISEASE. A STUDY OF ITS ADMINISTRATION IN TWENTY-TWO CASES *J. D. Hay* From the Royal Liverpool Children's Hospital and University of Liverpool, England. *Arch Dis Childhood* 23: 220-224 1948

It had previously been noted that although the macrocytic anemia associated with certain cases of coeliac disease responded favorably to pteroylglutamic acid, other types of anemia in such cases did not show any response to the material. The authors treated 22 children in whom they were able to establish a diagnosis of coeliac disease. None of these children apparently had fibrocystic disease of the pancreas. None of these cases had macrocytic anemia.

For a preliminary period of one to two months treatment consisted of a low fat high protein diet with added liver extract and vitamins. After this period pteroylglutamic acid was added to the regimen for a comparable period of time. The dose of folic acid was 20 or 10 mg. daily for one to two months. There was no particular change in the laboratory or clinical status of the patients on folic acid, and the author concluded that this material had no effect on coeliac disease in cases in which a macrocytic anemia (and megaloblastic marrow) were absent.

S E

CHRONIC HYPOPLASTIC ANAEMIA ARISING IN INFANCY *T. Robson and P. J. Sweeney* From the Royal Victoria and West Hants Hospital, London, England. *Arch Dis Childhood* 23: 294-296 1948

The subject of this report was pale at birth and showed at the time of initial examination at the age of 18 months pallor, slight hyponutrition, mental retardation and ptosis of one eyelid (which was present congenitally). The liver, spleen and lymph nodes were normal. The red cells numbered 1,230,000 per cu. mm., with a hemoglobin of 20 per cent (2.8 Gm.). The white cells and platelets were normal. Reticulocytes were virtually absent and a bone marrow aspiration showed a marked reduction of erythroid activity. A subsequent bone marrow biopsy showed absence of red cell precursors. Treatment was of no avail, except blood transfusions which were necessary and sufficient to maintain the child's blood at reasonable levels.

According to the authors there are very few reports of pure red cell anemia in the literature, perhaps 6 in children and 7 in adults. This report therefore is the seventh in a child. Of importance state the writers is possible spontaneous remission following repeated blood transfusion over a long period of time, hence continued treatment although without optimism is indicated.

S E.

SICKLE-CELL ANEMIA: ITS PATHOLOGICAL AND CLINICAL SIGNIFICANCE. *H. R. Pratt Thomas and P. A. Switzer* From the Departments of Pathology and Medicine, Medical College of the State of South Carolina, Charleston S. C. *South M J* 42: 376-384, 1949

Ten cases with necropsy findings are presented in which profound sickling of the red cells was the outstanding and often the only significant finding. None of the patients had active sickle cell disease. In several cases ischemic lesions were seen in the spleen, kidney or brain although thrombus formation was not demonstrable in the vessels supplying these areas.

The question is raised as to whether vascular obstruction is produced primarily by the masses of agglutinated sickle cells observed histologically or whether sickling and agglutination are merely secondary phenomena under conditions of stasis and anoxemia. Regardless of which is the initiating factor

these cases do emphasize the potential hazard of sickleemia in conditions producing lowered oxygen tension such as shock, anesthesia fever and congestive failure

H. W. B.

**RESPONSE OF LINGUAL MANIFESTATIONS OF PERNICIOUS ANEMIA TO PTEROYLGLUTAMIC ACID AND VITAMIN B<sub>12</sub>** J. F. Schieve and R. W. Rundles From the Department of Medicine Duke University School of Medicine Durham N. C. J. Lab. & Clin. Med. 34 439-447 1949

Two patients with pernicious anemia in relapse taking 30 and 50 mg. of pteroylglutamic acid daily developed acutely sore tongues with mucosal atrophy during the third month of therapy. The lingual mucosal atrophy of 5 patients with untreated pernicious anemia responded in five to seven days to injection of vitamin B<sub>12</sub>. The authors mention that in 6 of their patients treated with pteroylglutamic acid whose lingual responses were poor or who later relapsed, the blood levels remained below normal. Neurologic disease progressed in one and the red cell count fell significantly in another. They state in conclusion "The therapeutic limitations of pteroylglutamic acid in pernicious anemia relate to all manifestations of the disease — anemic, neurologic, and lingual—rather than to merely the neurologic."

G. E. C.

**BACTERIMETRIC STUDIES. III. BLOOD LEVEL STUDIES ON TEROPTEIN METABOLISM** G. Toennies and D. L. Gallant From the Lankenau Hospital Research Institute and the Institute for Cancer Research Philadelphia Pa. J. Lab. & Clin. Med. 34 501-508, 1949

Studies using *L. casei* and *Str. faecalis* of the fate of pteroylglutamic acid in human subjects indicated that two hours after intramuscular injection approximately two-thirds of the dose was present in the circulation. Of this total about two-thirds was present as the mono- and one third as the triglutamate. Subsequently the concentration of the monoglutamate declined more rapidly than the triglutamate. Different individuals showed considerable variations from the average metabolic pattern.

G. E. C.

**MEGALOBlastic ANAEMIA IN AN INFANT** J. H. Hutcheson and P. MacArthur From the Department of Child Health University of Glasgow and the Royal Hospital for Sick Children Glasgow, Scotland Lancet 1 916-917 1949

A case is reported of a girl who at 12 months developed severe anemia following enteritis. She responded to treatment with liver and iron but relapsed after a further attack of diarrhea and vomiting and was readmitted to hospital at 17 months. On investigation the anemia proved to be megaloblastic and responded to folic acid treatment.

S. C.

**THE MARCHIAFAVA MICHELI SYNDROME (PAROXYSMAL NOCTURNAL HAEMOGLOBINURIA)** J. Marks From the Department of Medicine University of Cambridge and the Bland-Sutton Institute of Pathology Middlesex Hospital London England Quart. J. Med. 18 105-121 1949

The authors present a thorough review of the literature and report 3 additional cases of Marchiafava-Micheli syndrome, bringing the total reported at the time of writing to 76. The review emphasizes the abnormality in the erythrocytes which undergo lysis by a thermolabile component of normal serum. Hemolysis is inhibited by sodium citrate, potassium oxalate, potassium cyanide, and heparin. The possible efficacy of pilocarpine nitrate in treatment is mentioned, a favorable influence on hemolysis apparently being observed in one case. The drug in this instance had to be discontinued because of undesirable side effects. Splenectomy is ineffective and is accompanied by a 40 per cent operative mortality in the cases where it has been attempted. Since hemolytic anemia without hemoglobinuria may dominate the clinical picture, the necessity of performing the specific serologic tests for this disease in any obscure hemolytic anemia is apparent.

W. N. V.

**ON PERNICIOUS ANEMIA IN MYXEDEMA** H. Esser and F. E. Schmengler Dtsch. Arch. Klin. Med. 193 431 1948

Three forms of anemia are seen in myxedema: (1) The uncomplicated myxedemic anemia (endocrine type); (2) the hypochromic anemia (endocrine type plus sideropenia); (3) (very rare) the hyperchromic form similar to pernicious anemia.

The author gives a description of a typical case of the third form. The following characteristics differentiate the myxedemic pernicious anemia from the typical pernicious anemia: (1) Unusually high color index (not treated 1.9), (2) inhibition of hemolysis, (3) inhibition of bone marrow activity, (4) course free from fever and relative bradycardia despite severe anemia, (5) normal or slightly reduced basal metabolism.

The endocrine disturbance prepares the way for pernicious anemia.

C M

INVESTIGATIONS OF THE RED CELL PICTURE UNDER THE CHRONIC INFLUENCE OF BENZENE AND ITS DERIVATIVES WITH SPECIAL REGARD TO THE DIAETER OF ERYTHROCYTE. *Karl Humperdinck and Alfons Abler* (Arbeitsmedizin. Institut Stuttgart/Tübingen.) *Aerzt. Forsch.* No. 5, 117-120, March 10, 1949.

Mixed solutions of benzene and its derivatives as used in industry damage the leukopoietic system and cause a moderate anemia of the hyperchromic type. This anemia is characterized by a slight increase of the average diameter of the red cells. Investigations based on 20 cases illustrate the diagnostic importance of this hyperchromic anemia as an early symptom.

C M

CELLS OF THE MEGAKARYOCYTE SERIES IN PERNICIOUS ANEMIA. IN PARTICULAR THE EFFECT OF SPECIFIC THERAPY. *R. D. Epstein* From the Thorndike Memorial Laboratory, Boston City Hospital, Boston. *Mass. Am. J. Path.* 35, 239-251, 1949.

In the past the many studies of pernicious anemia marrow during relapse have reported a decrease in megakaryocytes in general, and alterations in nuclear segmentation and lack of azurophilic granules in some instances. In the present study, marrow was aspirated from 5 patients before therapy was begun and again after the reticulocyte response had occurred. The number of megakaryocytes was estimated in terms of a million nucleated cells within about 20 oil immersion fields. Two general classes of megakaryocytes were recognized, viz. the mononuclear group and the group containing multiple nuclei in a single cytoplasmic mass. The latter are referred to as polykaryocytes of which there may be young, intermediate and mature forms. During relapse the percentage of polykaryocytes was high and that of the mononuclear megakaryocytes low. After remissions were induced by liver extract therapy the ratios were reversed. Whole blood and red cell concentrate transfusions did not produce this reversal. In other words the megakaryocytic system in pernicious anemia during relapse needs something other than an increase in the oxygen-carrying capacity of blood.

O P J

CHRONIC FAMILIAL METHEMOGLOBINEMIA AND A NEW MODIFICATION OF METHEMOGLOBIN. *H. Herlein and G. Weber* (Inn. Abt. der Stadt. Krankenhäuser Wuppertal-Elberfeld.) *Dtsch. Med. Wschr.* 1948, 476-478.

A family with methemoglobinemia is described in whose case, contrary to former observations, heredity was not recessive but dominant. Furthermore the pigment was not the usual methemoglobin but a new modification with a maximum absorption band at  $600\mu$ . The author believes that this variation is due to a specific change in the globin component of the hemoglobin molecule.

### The Second Congress Plans to Date

The Society will hold its Second Congress in Cambridge, England, August 21-26, 1950 Reports of plans and progress from President Sir Lionel Whitby, and Secretary-Treasurer of the 1950 Congress, Dr Martin Hynes, are indicative of an excellent meeting

Living accommodations are being planned at the University of Cambridge and in Cambridge The living quarters are being arranged to accommodate members and their families The Society will be glad to receive visitors who desire to attend

the Congress Applications for living quarters will be sent to those desiring such assistance at a later date

### LETTER TO THE EDITOR

The following letter has been received from Dr A Piney of London, England (For reference, see "Revised Nomenclature Pro and Con, *Blood*, June 1949, pp 776-782, for the original article, source of the discussion, see "Condensation of the First Two Reports of the Committee for Clarification of the Nomenclature of Cells and Diseases of the Blood and Blood-forming Organs, *Blood*, January 1949, pp 89-96)

TO THE EDITOR

I appreciate that you may not be able to publish an extensive correspondence on the proposed standardization of hematological nomenclature but I hope that you may be able to find space for a few brief remarks

(i) Those who, like myself can look back more than a quarter of a century will have noticed that there is far greater international agreement about the names of blood-cells than there used to be. This has come about by evolution in fact, by what Dr Wintrobe (p 777) advocates viz advancing knowledge rather than in too much concern about names

(ii) Dr O P Jones points out (p 777) that hematology is international in its scope and as a consequence, its terminology is not the property of any one country but in contradiction to this Drs Osgood Kracke and Heck assert "The problem seems sufficiently difficult to settle in *one* language at a time

Is not the only valid excuse for a terminology based on the classical languages that it can be international?

The proposals of Dr Osgood and his colleagues are such as to be quite useless to those who do not speak English. Rubriblast is a nasty etymological bastard but it is not so parochial a term that a Frenchman or a German could not understand it, but pernicious anemia type is incomprehensible to him

(iii) Even you Sir inadvertently demonstrate that evolution is a more satisfactory method of progress than is dictation. You say (p 782) "Certainly, consistency is always something to be applauded so why not use for leukemia the terms myelocytic lymphocytic and monocytic rather than myelogenous lymphatic and monocytic?" The answer to your question is of course that not all myelogenous leukemias are myelocytic or all lymphatic ones lymphocytic

A foolish consistency is the hobgoblin of little minds. Speak what you think to-day in words as hard as cannon balls and to-morrow speak what to-morrow thinks in hard words again.<sup>1</sup>

(iv) A Committee appointed by the Minister of Public Health in France has produced a nomenclature which is relatively simple and which does not represent a break with the history of hematology. Even so Chevallier<sup>2</sup> has published an alternative series of suggestions while attacking the quasi-official one sponsored by the Ministry

Are we not Sir in danger of being precipitated into the same sort of sterile arguments that filled hundreds of pages in the early volumes of the *Folia Haematologica*? And should we not do better to continue as in the past by defining our terms whenever necessary until some time in the future a labile but inherently stable terminology comes to birth, thus allowing us to avoid the risks of malformation that are inherent in all premature births?

*Bone Marrow Biopsy Hematology in the Light of Sternal Puncture* S J LEITNER (Switzerland) English Translation Revised and Edited by C J C BRITTON AND E NEUMARK of London Grune & Stratton New York 1949 \$8.50 433 pages

If one were to single out the one technique which has done most to advance the cause of hematology in the last two decades marrow aspiration would probably be well in the foreground. Despite this there has been a real dearth of good texts dealing with marrow biopsies. Britton and Neumark have therefore done a fine service for the English speaking medical profession in translating and revising Leitner's monograph. The result is a comprehensive 433 page work replete with hundreds of references to the current literature, 194 text figures and 6 color plates. The techniques and methods involved in sternal puncture are well described. Unfortunately there is no description of the sternal trephine biopsy nor of puncture aspirations at other sites, i.e. spinous process of the vertebrae, the iliac crest, etc.

The various marrow cells are carefully described. An unusual feature is a description of such matters as mitoses, maturation curves, karyokinetic curves and abnormal cell division.

Excellent descriptions are given of the marrow in pernicious anemia, idiopathic hypochromic anemia and in such miscellaneous disturbances as the anemia of hemorrhage, infection and nephritis. The descriptions of the marrow in polycythemia vera and aplastic anemia are by no means as comprehensive, however, and below the standards set for thrombocytopenic purpura and tumors.

Descriptions of individual cells are excellently done. The color plates show excellent color reproduction. On the other hand, some of the photomicrographs of single cells leave somewhat to be desired and could have been arranged with more uniformity. The bibliography is exhaustive and references to the literature are not only well chosen but complete.

This book is the first comprehensive text on marrow aspirations and as such should be required reading for all those having any interest in clinical and investigative hematology.

VOL IV, NO 10

OCTOBER, 1949

### STUDIES ON HYPOPROTEINEMIA II FAMILIAL IDIOPATHIC DYSPROTEINEMIA

By F HOMBURGER, M D, AND M L PETERMANN, PH D

THE PRESENT paper describes a new familial syndrome characterized by subtle disturbances of the qualitative relationship of the components of the blood plasma proteins and by a number of clinical disturbances

The patients comprising this study provided a unique opportunity to investigate mechanisms of the homeostasis of plasma proteins in individuals not afflicted with any of the common pathologic causes affecting the metabolism of plasma proteins. Studies were thus possible on the homeostasis of plasma proteins, i e, the factors which maintain uniformity or stability at the normal levels

In view of the many factors which tend to unbalance the equilibrium of plasma proteins this homeostasis is remarkably effective, yet little is known regarding its mechanisms. The known facts may be summarized as follows. Deviations from the norm (euproteinemia) may result in hypoproteinemia, hyperproteinemia, dysproteinemia and paraproteinemia—the last two terms meaning a disproportion between components usually occurring in blood plasma (dysproteinemia) and the presence of proteins not usually found in blood (paraproteinemia). A combination of any of these disorders with each of the others is of course possible. Thus, in multiple myeloma hyper-, para-, and dysproteinemia may coexist,<sup>17</sup> and gastric cancer<sup>18</sup> may cause hypo- and dysproteinemia (hypoalbuminemia). A similar picture is found in nephrosis.<sup>6</sup> In Addison's disease,<sup>19</sup> one may find dysproteinemia with normal total protein levels or with hyperproteinemia, and in dehydration hyperproteinemia may exist without disturbance of the proportional relationship of plasma components. With the exception of dehydration and of the production of Bence Jones protein in multiple myeloma, the mechanisms causing these disturbances are poorly understood. Even in the relatively simple case of hypoproteinemia the mechanisms are complex. It may occur because the circulating blood is inadequately supplied with protein or because too much of it escapes. Insufficient protein enters the blood stream in malnutrition or intestinal malabsorption or in defective synthesis of proteins (liver disease,<sup>20</sup> Cushing's syndrome<sup>4</sup>). Protein

From the Departments of Clinical Investigation and Protein Chemistry, the Sloan Kettering Institute for Cancer Research, Memorial Cancer Center, New York. This study has been aided by grants from the Teagle Fellowship Foundation, the National Cancer Institute, the Finney Howell Research Foundation, and the James Foundation of New York, Inc. With the technical assistance of Lee Burnett, Iris Forbes, Anita Ursloff, and Charlotte Pann. The electrophoretic analyses were performed by F P Hogness and Barbara Brodsky Gottlieb.

is lost in excess from the blood stream in nephrosis,<sup>5</sup> in altered vascular permeability, as in burns,<sup>6</sup> or with excessive catabolism of proteins, as in hyperthyroidism, uncontrolled diabetes mellitus<sup>8</sup> and pyrexia

A more complex type of hypoproteinemia which persists in the presence of tissue protein repletion occurs in patients with gastric cancer,<sup>9</sup> in chronic tuberculosis,<sup>10</sup> and in certain types of kidney disease.<sup>11</sup> In another group of cases the hypoproteinemia is unexplained and is therefore designated idiopathic hypoproteinemia.<sup>12-16</sup>

It appears from the preceding discussion that a theory of simple depletion alone cannot explain all of these phenomena.<sup>20-21</sup> Although many aspects are still but little understood, an approach to some of them is possible in favorable circumstances.

In the patients studied by us, a number of physiologic factors governing the homeostasis of single protein components have been observed. There were none of the usual systemic disorders leading to changes of the protein pattern and, except for the dysproteinemia and idiopathic hypoproteinemia in some cases, the individuals were healthy.

A detailed description of the clinical syndrome is necessary for the proper interpretation of the experiments to be described.

## PART I THE CHARACTERISTICS OF THE SYNDROME AND ITS FAMILIAL ASPECTS

After the clinical studies described below, it became evident that the subjects studied presented a new syndrome, for which the name familial idiopathic dysproteinemia is proposed. The syndrome is characterized by the familial occurrence of edema of the legs, with ulcers in the males and functional vascular changes in the females, by dysproteinemia of variable types and sometimes discernable only by electrophoresis, by a number of congenital malformations and by a high incidence of stillbirths. No etiologic factor was found.

### *Methods of Study*

A complete history was taken in each available member of the family and checked against that given by every other member. A complete physical examination was made of each available member. Whenever possible routine studies of renal, hepatic,\* cardiovascular (including oscillometric studies by means of the Collins oscillometer), gastro intestinal and adrenal<sup>22-27</sup> function were carried out. In the case of some patients special tests were employed. These included liver biopsy through an abdominal incision in one case (Case 8) and muscle biopsies for study of blood vessels in two cases (Cases 5 and 8) as well as measurements of the renal clearance of glucose, para aminohippuric acid and mannitol.<sup>28-30</sup> Glucose tolerance tests<sup>31</sup> and nitrogen, phosphorus and potassium balance studies<sup>32</sup> were performed on the metabolic ward.

The total plasma protein concentration was measured by Kjeldahl analysis and corrected for non-protein nitrogen. Plasma volumes were estimated by the Evans blue method.<sup>33</sup> The volume of the extracellular fluid space was estimated by the use of thiocyanate.<sup>34</sup> The electrophoretic technique used in this study has been described elsewhere.<sup>35</sup> Unless otherwise specified a veronal-citrate buffer at pH 8.6 and ionic strength 0.10 was used. Electrophoresis was performed on samples of plasma obtained from the patients

\* In the liver function tests the following methods were employed: measurement of hippuric acid excretion,<sup>36</sup> retention of bromsulfalein,<sup>37</sup> cephalin flocculation test,<sup>38</sup> and thymol turbidity test.<sup>39</sup>

TABLE 2—Case 8 Tabulation of Total Protein Concentration Albumin Concentration and Protein Intake from December 1945 to October 1947

Plasma means the 975 cc. of plasma injected at that time containing 6.15 Gm of protein per 100 ml. Notice that the actual (electrophoretically measured) albumin is considerably lower than that measured by the Howe method. The Howe albumin roughly corresponds to the sum of the electrophoretic albumin plus the globulins.

† Plasma vol ~360 ml

in the postabsorptive state. Since values for the various protein components given as percentages may be misleading when the total protein concentration is low, the concentration of each component is given in grains per 100 ml. of plasma. The amino acids of plasma and urine were studied by chromatograms on paper<sup>26</sup> and no abnormalities were found.

The composite family history is indicated in the genealogic table in figure 1. The strong physical resemblance between some of the members of the family is evidenced in figure 2.

The mother, now 70 years old and a cardiac patient, had suffered from ankle edema since the age of 50. There were consistently large families on her side as well as on her husband's in both their generation and the preceding one. In contrast to that, she had only 6 living offspring out of 11 pregnancies. The still-born fetuses were described as edematous about 7 months old and uremic poisoning was given as the presumed cause of death. A stillbirth also occurred in the subsequent generation presumably in the third month of pregnancy. No information was obtained regarding this fetus.

The father's family history reveals 3 surviving brothers: one with long-standing edema of the legs, presumably due to varicose veins, and 2 with prominent floating ribs. The father had edema of the legs,

at times severe enough to be incapacitating, he underwent a number of operations for varicose veins. He died of dropsy at the age of 52, following a cholecystectomy. He had a double vortex pilorum, a malformation recurring in several of his offspring (V in fig. 1).

Eighteen members of the family are included in the present study. Eleven of these were examined at home and blood taken for electrophoresis (Cases II H, II M, 3, 4, 6, 10, 11, 12, 14, 15). Five were hospitalized (Cases 1, 5, 7, 8, and 9) for studies lasting from 1 day (Case 1) to 1 year (Case 8). Two were not seen (Cases II N and 2), the histories being obtained from relatives.

In 9 of these subjects ankle edema was present. It is of interest to note that none of the patients who were prepubertal or at puberty (Cases 10, 11, 12, 14, 15) had ankle edema, even though dysproteinemia existed in 3 of them (Cases 11, 14, and 15). The onset of edema in all of those affected had always been after puberty. Some form of dysproteinemia was found in all patients with edema. Of 7 adult males, 4 had ulcers of the legs or a history thereof.

The following physical signs were found. All adult males in generation III (Cases 3, 5, and 6) had ulcers of the legs at some time in their adult life. All adult females in generation III (Cases 4, 7, and 8) had low oscillometric indices in the upper extremities. Protruding floating ribs were seen in 11 subjects (Cases

II L, II M 3 4 5 7 8 10 12 14 15) Double vortices pilorum existed in 4 individuals 3 males and one female (Cases 2 5 9 and 15) scattered through 3 generations

#### Laboratory Studies (Tables 5 and 8)

Laboratory studies revealed the following Hypoproteinemia existed in 4 cases (Cases 5, 8, 9 and 14), ranging from 4.7 Gm per 100 ml to 6.0 Gm per 100 ml (The normal range in our 13 controls was from 6.1 Gm per 100 ml to 7.9 Gm per 100 ml) Dysproteinemia was found in 10 cases (Cases 5, 6, 7, 8, 9, 11, 14, 15, II L and II M) The changes found in the mother (Case 1) and in one of her daughters (Case 7) may be insignificant, and in Case 6 the marked abnormalities reverted to normal after 6 months In all the others, dysproteinemia was present beyond doubt A single component was altered in 7 instances ( $\alpha_2$ , in Cases II L, II M, 7 and possibly Case 5, albumin in Case 9 and possibly Case 1, and  $\gamma$ -globulin in Cases 11 and 14) \* Two plasma components or more were altered in 3 cases (Case 5, albumin,  $\alpha_2$ , and  $\gamma$ -globulin), Case 6 showed  $\alpha_2$  and  $\beta$  markedly changed on one occasion on repeated analyses in two different buffers Six months later, no abnormalities were uncovered by electrophoresis Case 8 repeatedly had a low albumin and exceedingly low  $\gamma$ -globulin values In Case 14 there was a low  $\gamma$ -globulin and a low albumin) \*

TABLE 4 —Kidney Function Tests in Case 5 and Case 8

	Mannitol (glomerular filtration) ml/min	PAH (renal plasma flow) ml/min	Glucose Tm mgm/min.
Normal Range	90-120	500-700	250-350
Case 5	107	645	322
Case 8	117	540	276

This represents a wide variety of alterations in the concentration of individual components of plasma protein with only one combination of changes (albumin and  $\gamma$ -globulin) occurring in more than one patient

Routine clinical laboratory findings were normal in all subjects studied Blood chemical examinations other than plasma protein levels (vide supra) were within normal limits There was a tendency to hypochlorhydria in the 3 subjects studied (Cases 5, 7 and 8) and no response to histamine in one case (Case 5) but proteolytic enzymes were present in the gastric juice of all patients The hematologic examination gave a normal picture, there was a tendency to low white counts but none fell below the normal range

Urine examinations were consistently normal and no proteinuria could be demonstrated by any of a number of methods

The renal clearance studies (table 4) and the adrenal function tests gave normal responses All liver function tests (table 3) gave negative results excepting in Case 8, in which liver functions were disturbed in the course of a severe homologous serum hepatitis This was followed by a return to normal function as measured by

\* Interpretation of the electrophoretic data in Cases 14 and 15 was difficult because of cloudiness caused by a meal being taken before venipuncture The patterns were fairly normal for children of this age <sup>27</sup> except for the changes noted

the tests. In Case II L, there was a history of alcoholism and clinically liver disease could be suspected but no liver function tests could be carried out.

Muscle biopsies showed normal blood vessels and lymphatics (fig 4) and the special stains and numerous sections studied on the liver biopsy material taken from Case 8 failed to reveal any morphologic change (fig 4).

## PART II STUDIES ON THE NATURE OF THE DEFECTS OF PROTEIN HOMEOSTASIS IN FAMILIAL IDIOPATHIC DYSPROTEINEMIA

The following studies were made on the nature of the alterations of the plasma proteins.

1. A nitrogen balance study was made in Case 8. This patient was maintained in positive nitrogen balance for a considerable length of time, during this period her total circulating plasma protein was measured repeatedly.

2 In the same patient, the rate at which the increased albumin concentration returned to normal following the intravenous injection of human albumin was determined by measuring plasma volume and albumin concentration<sup>38 39</sup> before and after the injection of human serum albumin

3 In the same case, the rate at which  $\gamma$ -globulin concentration returned to normal following the injection of plasma containing a normal amount of  $\gamma$ -globulin was determined This was possible because the initial concentration of  $\gamma$ -globulin in the plasma was very low Nine hundred and seventy-five ml of pooled plasma were injected and the  $\gamma$ -globulin concentration before and after the plasma infusion was followed by electrophoretic studies and also by immunologic methods to be reported later<sup>40</sup> The results of the electrophoretic procedures were subjected to certain calculations before evaluation \*

\*  $\gamma_1$  is the globulin component of serum which has the mobility of fibrinogen. (Biophysical studies on blood plasma proteins IV Separation and purification of a new globulin from normal human plasma Deutsch H F Alberty R. A, and Gosting L. J. J Biol. Chem., 165 31-25 1946)  
† Serum

4 In the same patient, the effect on the plasma protein concentration of the acute withdrawal of 500 ml of blood and reinjection of the cells into the donor was studied (protein subtraction test<sup>41</sup>) After a base-line sample had been taken, 500 ml of blood were removed, centrifuged in a closed system and the red cells separated from the plasma The cells were suspended in 10 per cent dextrose solution to make a total volume of 500 ml and immediately reinjected The plasma protein concentration was then followed<sup>42 44</sup>

\* From the data of Perlmann and Kaufman<sup>41</sup> and of Armstrong Budka and Morrison<sup>42</sup> it may be calculated that the  $\gamma$  globulin values obtained under the conditions used in these experiments (—15 per cent protein and ionic strength 0 10) are 25 per cent too low Further correction was made for variation in nitrogen content and refractive index increment among the various plasma protein components Since these corrections increase the  $\gamma$ -globulin concentration of normal plasma from 6 8 to 8 0 grams per liter<sup>43</sup> an additional correctional factor of  $\frac{8.0}{6.8}$  has been applied here The total correction is thus  $1.5 \times \frac{8.0}{6.8} =$

5 The ability of this patient to form certain antibodies was tested in collaboration with Drs M Heidelberger, E A Kabat and A Bendich. The formation of antibodies against pneumococcus polysaccharides was tested in Dr Heidelberger's laboratory by the method he has described.<sup>48</sup> The formation of anti A isohemagglutinin was tested by Drs Bendich and Kabat, using an antigen (A agglutinin) that has been assayed with positive results in 9 normal adults.

### Results

1 A considerable amount of nitrogen, phosphorus and potassium were retained by this patient during the 18 days of the balance study (table 1, fig 5). The concentration of the plasma protein, however, remained the same throughout this period. Table 2 further demonstrates that throughout two years of observation, her plasma protein remained low while her protein intake had been high.

2 Figure 6 shows that this patient initially retained slightly more injected albumin than a normal control of the same age and sex but that the slope of the disappearance curve was parallel to that in the normal subject.

3 The rate of disappearance of the injected  $\gamma$ -globulin as measured by the immunologic methods was rapid, with a half-life of immunologically specific circulating  $\gamma$ -globulin of 3-5 days. The disappearance rate as determined by electrophoresis (table 6) was slower but agreed with the immunochemical results within the limits of error of the electrophoretic method, which is large for the measurement of such a small component.

4 The result of the protein subtraction test was obscured by the fact that the sample taken 24 hours after bleeding was hemolyzed, due to difficulties in venipuncture in this patient; consequently, the extent of the fall of the plasma protein concentration following plasmapheresis could not be evaluated. There was a clear-cut increase of plasma protein 48 hours after bleeding, even more marked than that found in normal individuals (fig 7).

5 The production of antibodies against pneumococcus polysaccharides was definitely weak and no anti-A isohemagglutinin was formed following the injection of an agglutinin.

In summary, one patient (Case 8) failed to elevate her reduced plasma protein level while maintained in positive nitrogen balance by a high protein intake. She showed no defect in her ability to handle injected human albumin and in her ability to regenerate plasma protein following acute withdrawal. Studies on the rate of disappearance of injected  $\gamma$ -globulin were inconclusive. No antibody response was obtained to 2 specific antigens.

### Discussion

Although the presenting features of this syndrome are the marked edema in males and females and ulcers of the legs in males, in no case was the amount of albumin or total protein lowered to the extent that is usually required to produce edema. Therefore, the pathogenesis of this part of the syndrome must be sought elsewhere, such as in a defect of the vascular system, since adrenal and renal mechanisms were found to be intact. In view of the multiple congenital malforma-

tions uncovered in this family, one is tempted to consider a constitutional inferiority of the vascular system. However, systemic humoral mechanisms affecting the vascular system have not been excluded. The lowered oscillometric indices in the arms of 3 females and the markedly hypoplastic veins in one of them tend to strengthen this concept, even though muscle biopsies in 2 patients did not show morphologic vascular changes.

The existence of a clinical entity wherein such cryptogenic edema is coupled with subtle changes in the proportion of electrophoretic components of the blood

† Old Nomenclature Rh<sub>0</sub>, Rh', Rh'', H<sub>0</sub>'. New Nomenclature D, C, E, c (On the Nomenclature of the Anti Rh Typing Serums. Report of Advisory Review Board. William B. Castle, Maxwell M. Winterrope and Laurence H. Snyder. *Science* 107: 27-31, 1948.)

‡ Homozygous and heterozygous refer only to the antigenic constitution of the C factor and on statistical probability also to the D factor. No abnormal antibodies were found in the plasma of the wife of this patient 6 months after a stillbirth.

plasma has been established, it is to be expected that more such cases will be found. In this event, the family history should be carefully investigated, as the familial occurrence of this disorder was the most striking feature of this group of patients. The co-existence of congenital malformations, frequent stillbirths (mother Rh positive), and dysproteinemia coupled with constitutional inferiority of the vascular system suggest very strongly the possibility of genetic etiologic mechanisms. This assumption seems even more likely in view of the known hereditary transmission of hemophilia and fibrinogenopenia, both of which appear to be mediated through a lack of certain components of the plasma proteins.<sup>48-49</sup> The hereditary mechanisms governing hemagglutinins, another type of plasma protein component, are well established.<sup>50</sup>

The connection between appearance of edema and puberty, as well as the frequency of stillbirths without Rh immunization (table 7), suggest the possibility of sex hormone disturbance. This may or may not have etiologic or pathogenic significance.

So far, the etiology of the syndrome as well as the pathogenesis of the edema remain obscure. We feel that all known organic causes have been eliminated.

Some information, however, has been gained on the pathogenesis of the disturbed homeostasis of plasma proteins. The pictures observed electrophoretically were (with the possible exception of Cases 7 and 11) striking and significant. In some cases (Cases 6 and 8), the analyses were run in a variety of buffers, so as to exclude changes in mobility of the protein that might be due to an abnormal affinity for citrate iron.

In the case of the mother (Case 1), the slight hypoalbuminemia observed at first examination had disappeared on the second examination, nearly a year later. There is some question whether the lowered albumin may not have been due to congestion of the liver, as the patient had signs of cardiac infarction at that time. In Case 6, the marked changes that had been found in two different buffers at the first examination had disappeared on second examination. The patient still had marked ankle edema but the ulcers of the legs present when the first blood had been drawn had healed.

Some of the plasma protein patterns were most unusual. We are aware of only 2 cases in adults that resemble the pattern found in Case 8 (fig. 3). In one case this marked defect of the  $\gamma$ -globulin was on a nutritional basis,<sup>41</sup> and in a second case<sup>42</sup> liver disease was not ruled out and there was a history of chronic alcoholism. Two additional comparable patterns have been reported in children,<sup>43</sup> one of them a definite case of idiopathic hypoproteinemia.<sup>18</sup>

The statistical significance of the changes in  $\gamma$ -globulin in Cases 5 and 8 has been

analyzed in comparison with a group of 13 normal individuals by Dr. J. W. Tukey, Princeton University, and his comments follow.

The 13 normal cases have a mean  $\gamma$ -globulin (in Gm/100 ml) of 0.78 and a standard deviation of 0.106. This compares well with Dole's<sup>54</sup> mean of 0.74 and standard deviation of 0.151 (for 15 cases). If we are prepared to assume that the distribution of amounts of  $\gamma$ -globulin in normal persons follows the so-called normal or Gaussian law, we can set tolerance limits of the form (sample mean)  $\pm \bar{K}$  (sample standard deviation) in such a way that there is a 75 per cent probability that 999 normal cases in 1000 fall between these limits. Values of  $\bar{K}$  are tabulated for different numbers of cases and different probability levels in Eisenhart, Hastay and Wallis<sup>55</sup> at pages 102-107. For 13 cases and the probability levels chosen above  $\bar{K} = 4.059$ .

It seems reasonable to suppose that, while the distribution of  $\gamma$ -globulin may be somewhat skew, with a longer tail toward higher values, the distribution of the logarithm of  $\gamma$ -globulin will be symmetrical, or skewed toward low values. Thus, if we set tolerance limits based on both  $\gamma$ -globulin and on the logarithm of  $\gamma$ -globulin, and then use the outermost limits, we are likely to have a reasonable chance of being conservative. The results are as follows.

*Tolerance Limits for  $\gamma$ -Globulin Concentration in Gm/100 ml based on 13 Normal Cases*

Assumption	Range with 75% probability of covering 999 in 1000
$\gamma$ globulin normally distributed	0.34 to 1.22
Logarithm of $\gamma$ globulin normally distributed	0.43 to 1.37
Conservative recommended	0.34 to 1.37

It will be noticed that the single determination on Case 5 and all 5 determinations on Case 8 fall outside the conservative limits.

The occurrence of such extreme changes is convenient, since by the simple administration of normal plasma one is able greatly to increase the concentration of the deficient plasma component and may then follow its disappearance from the circulation. In Case 8 the injected  $\gamma$ -globulin disappeared rather rapidly and a mechanism seemed to exist that maintained the  $\gamma$ -globulin at its set level far below normal. In an unpublished case of Dr. E. Short, with a sprue-like syndrome, complicated by a history of an earlier disease of the lymphoid tissue, a similar curve of disappearance of  $\gamma$ -globulin was obtained (an autopsy later revealed generalized giant follicular lymphoblastoma). The half-life of the immunologically specific  $\gamma$ -globulin was considerably shorter than the half-life of the glycine labeled  $\gamma$ -globulin as measured by Rittenberg and Shemin (quoted in ref. no. 45). It is impossible for us to offer an interpretation of these facts at the present time.

Evidence was obtained, however, that in one patient (Case 8), a defect existed in the fabrication of circulating antibody against pneumococcus polysaccharide and A agglutinin. A similar defect in synthesis, combined with a homeostatic mechanism set for subnormal levels, may exist for other components. Following the

injection of albumin, its concentration returned to the subnormal preinjection level at a normal rate,\* whereas in Case 7 plasma protein infusions resulted in one instance in a normal protein level for several weeks

In 2 cases the general condition of the patient was improved by the administration of plasma and the edema tended to regress even though the initial hypoproteinemia had been moderate (Cases 7 and 8) In Case 5 no beneficial effect was observed following plasma infusion

The failure of one patient to increase the plasma protein concentration while repleting tissue protein (Case 8) resembled the condition found in hypoproteinemic patients with gastric cancer,<sup>19</sup> tuberculosis<sup>10</sup> and certain types of renal disease<sup>11</sup>

### SUMMARY

1 A new syndrome, *idiopathic familial dysproteinemia*, is described in 4 adult members of one generation, in 2 of their paternal uncles and in 4 members of the second generation The syndrome is characterized by hypoproteinemia and/or abnormalities in the electrophoretic patterns of the blood plasma (dysproteinemia) These are accompanied in the adult by peripheral vascular changes (ulcers of the legs in the men, low oscillometric indices in the women) and edema There are also malformations of the thoracic cage and of the occipital hair distribution in some of the cases

2. The idiopathic nature of the disease was ascertained in some of the patients by study of the nutritional history, of the renal, hepatic and adrenal functions, and of the response to a high-protein diet under controlled conditions

3 In one case detailed studies of the mechanisms of plasma protein regulation resulted in findings that indicate a disturbance in the production of certain protein components The disappearance rate of injected albumin and the rate of replacement of acutely withdrawn plasma protein were normal

4 The clinical and physio-pathologic significance of this syndrome and the possible role of genetic factors are discussed

### APPENDIX CASE HISTORIES

#### (Generation II Fig 1)

1 This white woman aged 70 is the mother and grandmother respectively of some of the other patients herein described

Chief complaint swelling of ankles since age of 50 accentuated in the last five years. There was dyspnea, orthopnea and tachycardia Past History five years ago there was an increase in ankle edema with progressive fatigue dizziness and headaches Her family physician found an elevated blood pressure.

Physical examination B P 135/95 pulse 90 There was a moderately enlarged liver obesity ankle edema and rales in both lung fields Laboratory findings the electrocardiogram showed signs of recent infarction and auricular fibrillation the urines were negative the blood picture was negative The liver function tests were as follows prothrombin time 81 per cent cephalin flocculation and thymol turbidity negative Protein studies have been described above

Course the patient was not hospitalized and was doing well under routine care by her local physician when last heard from

---

\* Dr F Albright reports recent metabolic studies in an isolated case of idiopathic hypoproteinemia demonstrating an increased rate of combustion of injected albumin

II H. White woman aged 65, only surviving sister of preceding patient was examined in her home. Her past history was negative. She has 4 children who are in excellent health. Physical examination negative except for a B P of 16/100 which was not causing any symptoms.

II L. An obese white male of 63, one of 3 surviving brothers of husband of Case 1. He was examined at his home and was rather vague about his past history. Twelve years ago he had swelling of the ankles and later an attack of gout. He admitted a fairly high alcoholic intake. Physical examination revealed telangiectasis on face and thorax and pityriasis rosea on thorax. The edge of the liver was palpable 3 finger-breadths below the costal margin in the mid-clavicular line. The floating ribs were markedly prominent.

II M. A white male aged 72, brother of preceding. He had always been in good health except for an episode of pulmonary tuberculosis in early life until 5 years ago when he began to suffer from back pain which became intolerable. Studies at Johns Hopkins and in other university hospitals failed to reveal

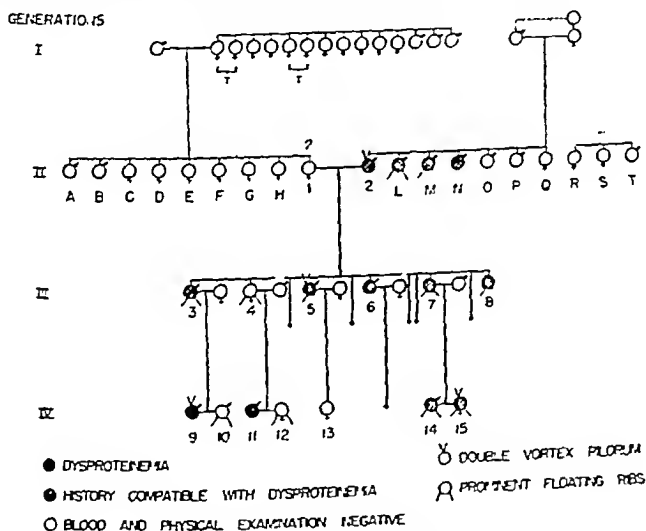

FIG 1—GENEALOGIC TABLE

any enology except osteoarthritis of the spine and an exploratory laminectomy was negative. Physical examination revealed a well-developed and well-nourished white male bedridden with severe back pain. There was a scar of an old lumbar laminectomy and the left wing of the sacrum seemed more prominent than the right and was tender on palpation. There were markedly prominent floating ribs. On the right hand there was a Dupuytren's contracture. The remaining physical examination was negative. Complete laboratory studies could not be done but serum phosphatases and phosphorus were within normal limits.

II N. A third brother of the 2 preceding patients is said to have suffered from edema of the legs during all his adult life. Unfortunately it was not possible to reach him personally at the time of this study.

2. The father of some of the patients described and the husband of Case 1 died at the age of 55 from dropsy following a cholecystectomy. He had edema of the legs at an early age and at times had to use crutches. Repeated vein ligations had to be done for phlebitis of the legs. There are no hospital records to substantiate this history. He had a double vortex pilorum. His family history was not contributory. He had had 6 brothers and one sister and there was a history of tuberculosis at an early age in 2 of these individuals.

*(Generation III Fig. 1)*

3 A white male of 48 tall and thin with grey hair looking somewhat older than his chronologic age. He had had mumps, measles and chicken pox but remembered no diseases in adult life other than an episode of phlebitis 3 years ago with a small ulcer of the leg. Physical examination showed markedly prominent floating ribs, a blood pressure of 120/60 and 1 plus pitting edema of both ankles. The skin over the ankles and the lower part of the calves was thin and atrophic. There was a dark brownish discoloration on the external and internal aspect of the right ankle. Body hair was scant. The remaining physical examination was negative.

4 The history of this well-developed stout woman, sister of preceding patient, was negative. She has enjoyed remarkably good health except for vasomotor disturbances of hands and feet with episodes

FIG. 2.—FAMILY PHOTOGRAPH

of cold and clamminess. Physical examination revealed normal blood pressure but exceedingly low osmometric indices (1-2) in both arms. There was marked prominence of the floating ribs. There was mild edema of the ankles, less evident than in the photograph shown in figure...

5 (MH 8409-Sk 1 163) White man aged 41, brother of the preceding patient. His chief complaint, swelling of the legs, started an unknown number of years ago, and the patient has been using elastic stockings ever since. In 1944 large ulcers appeared on the right lower calf and caused what was termed a deep phlebitis. Saphenous vein ligation was then performed. The right leg has persistently remained more swollen than the left one.

The past history contained a story of swelling of both legs at the age of 8 months, followed by atrophy making walking impossible until the age of 19 months. In the absence of persistent sequelae it was difficult to accept the diagnosis of poliomyelitis then made. There were numerous episodes of infectious

diseases 4 recurrent bronchopneumonias between 1909 and 1911 tonsillectomy in 1915 appendicitis with peritonitis in 1931 The patient gained a great deal of weight from 1939 to 1946 when he weighed 275 lbs He was 6 ft 7 in tall He lost 50 lbs on a reducing diet but regained 20 lbs on the well balanced food intake he had had for several months before admission

Physical examination revealed a white male of tall build He wore shoes size 14 his feet were thus large even for his stature Physical examination was negative except for pitting edema of both legs with brownish discoloration around the ankles bilaterally There was an abdominal scar in the lower quadrant The floating ribs were protruding and there was a double vortex pilorum There was complete edentia The visual acuity was poor bilaterally and there was an early cataract on the right eye (Dr B F Payne) The ophthalmologist found the fundi and visual fields bilaterally normal

FIG 3—Electrophoretic patterns obtained in veronal-citrate buffer on plasma from a representative normal subject and from three patients 6 corresponds to 6a and 8 to 8b in table 5

Laboratory studies chest x ray was negative and no anomalies were seen in lateral pictures of the skull

Basal metabolic rate several tests were done but the patient was resistant to the procedure and the results while within normal limits were inconclusive

Hematology hemoglobin 12.7 Gm White blood cells 3 850 filamented 44 per cent nonfilamented 1 per cent eosinophiles 3 per cent monocytes 3 per cent lymphocytes 46 per cent

Serology Mazzini tests were negative

Urinalysis urines showed no protein on repeated tests and no other abnormal findings

Gastric analysis showed no free acid before or after histamine Liver function tests these were all negative and the results are shown in table 3

Renal function tests showed no evidence of renal damage (see table 4) Cardiovascular tests blood pressure 125/85 pulse 75 temperature 98.7 Electrocardiograms were negative The oscillometric readings of arms and legs were normal The circulation times by decholin were 20 seconds by ether 15 seconds

The venous pressure was 16 cm of water. Chemical studies of blood are shown in table 7 and are within normal limits. The disturbances of the plasma protein pattern are shown in table 5. In this case there was mild hypoproteinemia and a marked disturbance of the globulin fractions.

Histopathologic studies: serial sections of muscle revealed no morphological anomalies of blood vessels (Dr S. Spitz) (fig. 4).

FIG. 4.—*Top*: microphotographs of liver and muscle in Case 8. Note normal appearance of all structures. *Bottom*: biopsy of muscle in Case 5. Normal blood vessels.

**Course of disease.** The patient remained in the hospital for one week only. He left to resume his work as a travelling salesman. The only functional study on his protein metabolism was the administration of 75 Gm. of albumin intravenously. The test could not be carried out completely because of a severe pyrogenic reaction with chills and high temperature. However, about one third of the injected dose was still present in the circulation after 24 hours.

6. This white man aged 38 was seen at his home. He suffered from boils on his head in infancy and had whooping cough at the age of one year. At the age of 8 (1918) he had influenza, followed by chicken pox and roscola. At the age of 15 he had a serious attack of mumps and later on episodes of chronic appendicitis. He was always subject to skin rashes and is sensitive to poison oak. A dark brownish discoloration of both ankles made its appearance at the age of 15. At the age of 20 (1930) the first ulcers of

the leg appeared and kept him bedridden for six months. Ulcers of the legs recurred in 1935, 1938, 1939, 1940, 1943, 1944, 1945, 1946 and 1947, taking each time from some weeks to several months to heal. During a brief period of military service there was an episode of pyuria attributed to infected teeth.

Physical examination revealed brownish discoloration around both ankles, hypertrophy and desquamation of the skin in these areas, prominent floating ribs and no other changes.

Laboratory studies other than electrophoresis of blood were not performed.

7 (MH 86268-SK1 58) This patient is a white married woman of 33. She is the sister of Case 8 and her family history has been described above. She is the mother of 2 children aged 5 and 9 years (Cases 14 and 15).

Chief complaint: swelling of ankles of several years' duration. The patient had been hospitalized for this two years ago and was told that she had a lymphatic condition. She has had measles, whooping cough and chicken pox but like her sister never mumps. She has not lived with her sister for eleven years.

Two years before her admission to this hospital she felt that she was too fat (145 lbs) and reduced on a regime of low dietary intake, dextroline and thyroid. She has continued to take  $\frac{1}{2}$  to 1 gr daily of thyroid since then with no particular indication. Once her weight had stabilized at 132 lbs she returned to a well-balanced and adequate food intake and did not regain her overweight.

There was no history of any disease during her adult life except for the swelling of her ankles which dates back to about the age of 16. This was complicated at one time by phlebitis following an infection of a toe. Systemic review revealed that she had always had cold and clammy extremities, recurrent mild headaches and constipation. Her menstrual history was normal except for menorrhagia for several months following her second pregnancy. Both deliveries were at term and normal.

Physical examination completely negative except for the protrusion of the floating ribs resembling that found in some of the other siblings who were studied and for the marked edema of the ankles. There was also blue discoloration and coolness of the hands and feet. The oscillometric measurements in arms and legs were extremely low.

Laboratory studies: Chest x-rays were within normal limits. X-rays of the bones showed no anomalies. There was a small calcified area in the mid pelvis, possibly a mesenteric node or urethral calcification.

Basal metabolic rate  $-17 \pm 1$   $-20$

Hematology: see table 7

Serology: Mazzini, Kahn and Kline tests negative

Urinanalysis: urines were negative and no albumin was found at any time

Gastric analysis: fasting free acidity was 14 units and total acidity 34 units. This rose following histamine to 55 and 73 units respectively.

Liver function tests: bilirubin, cephalin flocculation, thymol turbidity tests and bromsulphalein retention all gave normal results.

Cardiovascular tests: electrocardiograms were normal.

Circulation times: decholin 16 seconds, ether 13.5 seconds. Venous pressure measured 17 cm of water. The oscillometric indices have been discussed.

Chemical studies of the blood fell within normal limits. The anomalies of the blood plasma proteins of this patient are shown in table 5.

Course of disease: this patient was able to remain in the hospital for only three days. A most remarkable fact was her response to the infusion of 25 Gm of human albumin. Even though no diuresis occurred her ankles decreased markedly in size during the night following the infusion. She was given one liter of human plasma before leaving the hospital and it was rather striking that the total protein level remained above 7 Gm per 100 ml for nearly one month. In spite of this however the ankle edema returned to its previous extent about 2 weeks after discharge.

8 (M.H. 83651-SK1 120) This patient was a white girl of 31, a personnel manager who was born and lived most of her life in the South. She came to work in New York City several years before her admission to Memorial Hospital. Since the age of about 16 she has suffered from swelling of the ankles and legs and from occasional facial edema.

Family history as described above

Past history the patient had the usual childhood diseases except mumps. She had repeated colds, four episodes of pneumonia as a baby and underwent tonsillectomy at the age of 13 which failed to decrease the frequency of colds and sore throats. There is a history of shoulder pains suffered as a small child and the patient still occasionally experiences dull pains in her shoulder girdle.

The systemic review reveals that she suffers from occasional headaches especially whenever she has one of her frequent colds. For a short period in 1944 she had daily elevation of temperature, but no lesions were seen on x ray of the chest and the temperature became normal. She was often rather tired and her swollen ankles were at times attributed to a cardiovascular disorder for which no objective evidence was ever obtained. She has had gingivitis and occasional gastrointestinal upsets. In the past two years, she has had nocturia occasionally once a night and there was usually some urgency for urination. There

Fig 5—Estimated Protein Distribution Case 8 Cross hatched areas show daily nitrogen retention cumulative nitrogen retention in last column presumably retained for protoplasm synthesis. Solid line at 28 Gm shows normal amount of plasma protein nitrogen (Seven Gm protein per 100 ml. plasma  $\times$  12 Gm nitrogen. This value times normal plasma volume of 2500 ml = 28 Gm.) Full columns show amounts of circulating protein nitrogen found in patient.

was no history or evidence of venereal infection. She started to menstruate at the age of 13 and had a 30-day regular cycle, periods lasting 5 days and slight abdominal pains preceding menstruation with occasional mastodynia at the same time. There was no history of disturbed endocrine function. She was allergic to various foods which caused urticaria to appear; she showed fairly severe urticarial reactions following the administration of plasma. There was no history of severe gastrointestinal or hepatic disorder.

Physical examination revealed a well-nourished white girl of 31 of asthenic habitus. Blood pressure 105/76 pulse 95 temperature 99 F. The skin was moist and warm. In places especially over the upper and lower extremities there was some bluish discoloration (vasodilatation). There was mild seborrhea of the face and scalp. The hair was soft and brown. The finger and toe-nails were exceedingly thin and soft and detached from the nailbed at their tips to a more marked degree than is usually seen; all the nails showed longitudinal ridges.

The bones appeared to be of normal size and configuration except for the floating ribs which protruded more than is usually the case from the thorax. The joints were free from swellings or inflammation and no visible deformities were present.

There was no enlargement of lymph nodes. The ears, nose and throat were normal, the tonsils were absent. No anomalies were found in the eyes or extraocular muscles. The tongue showed slightly atrophic papillae and there was some loosening of the gums from the teeth which were in good repair. The trachea was in the midline. The thorax was symmetrical and clear to percussion and auscultation, the floating ribs protruded unduly. The breasts were small but firm and glandular tissue was distinctly palpable.

The cardiovascular system was normal on physical examination except for the peripheral veins which were extremely small, hardly visible even in infra red photographs or palpable in the antecubital fossae even though there was no excess of subcutaneous fat. There was also striking blue discoloration of hands

FIG 6—ALBUMIN ADDITION TEST IN CASE 8

\* ASSUMING CONSTANT PV

FIG 7—PROTEIN SUBTRACTION TEST

and feet. The oscillometric examinations of arms and legs showed markedly reduced oscillations, a finding which was to be expected in the edematous legs but which was also marked in both arms. There was pitting edema of both ankles and calves up to the knee.

The abdomen was soft and slightly protruding, there was no tenderness on palpation and no masses were felt. The gynecological examination revealed a normal vulva and vagina, a small uterus in the midline, retroverted and flexed but freely mobile, and normal annexae. The rectal examination was negative. The neurological examination was completely negative.

Laboratory studies: chest x-rays were repeatedly negative. Studies of all bones including the skull showed normal structure and bone age and specifically no signs of decalcification. A gastrointestinal series was negative. The only positive x-ray finding was a congenital lumbarization of the first sacral vertebra.

Basal metabolic rate  $+7$  on two occasions

Hematology from November 1946 to November, 1947 20 blood counts were done. The hemoglobin varied from 12 Gm to 15.6 Gm the red blood cells were 4.1 and 4.3 millions (they were not counted in all blood examinations) The white count varied from 4,750 to 6,900 filamented polynuclear cells from 59 per cent to 81 per cent non filamented forms from 1 per cent to 15 per cent eosinophiles from 1 per cent to 7 per cent monocytes from 1 per cent to 5 per cent and lymphocytes from 9 to 26 per cent. Hematocrits varied between 38 and 41 Metamyelocytes were seen on a few occasions Sedimentation rates were repeatedly normal Blood group and type are shown in table 7

Serology Mazzini Kline and Kahn tests were repeatedly negative Heterophile and Aborts Bang agglutination tests were negative

Urinalysis urines were acid except on one occasion No albumin was ever found either by the routine nitric acid test or with other precipitants such as sulfosalicylic acid trichloroacetic acid heat coagulation etc The centrifuged sediment contained occasional leukocytes and rare epithelial cells never any red cells

Stool examination the appearance of the stools was normal They were well formed, negative for fat blood and undigested muscle fibers No parasites were found The daily fecal nitrogen excretion never exceeded 10 per cent of the intake The fecal fat excretion was below 5 per cent of the intake

Gastric analysis this showed no free acid in a fasting sample and 18 units of total acidity After histamine there were 34 units of free and 40 units of total acidity On another occasion there were 64 units of total and 48 of free acidity following histamine and pepsin was repeatedly found to be present by digestion test

Liver function tests these are shown in table 3 An intravenous glucose tolerance test was normal

Renal function tests shown in table 4 Measurements of renal blood flow glomerular filtration and tubular re absorption were within normal limits Cardiovascular tests electrocardiograms were normal Circulation time by decholin was  $21\frac{1}{2}$  seconds by ether  $10\frac{3}{4}$  seconds The venous pressure was 20 cm. of water The oscillometric studies have been discussed

Tests of adrenal function a Robinson Power and Kepler<sup>6</sup> procedure clearly indicated the absence of Addison's disease The same result was obtained by the Cutler Power Wilder<sup>7</sup> test, as well as by that described by Reforzo-Membrives, Power and Kepler<sup>12</sup> Chemical studies of blood were within normal limits

Histopathologic studies a liver biopsy was performed in local anesthesia through an abdominal incision (Dr G C Child III) and slides showed normal hepatic tissue (Dr S Spitz) A muscle biopsy (rectus abdominis) taken at the same time and examined in serial sections showed no muscular or vascular anomalies

Repeated vaginal smears (Dr A. Carter) showed changes as seen in normal ovulatory menstrual cycle.

The anomalies found in the blood plasma protein patterns are shown above (table 5) The total protein was consistently low (Kjeldahl determinations) and the  $\gamma$ -globulin as measured by electrophoresis was the lowest value seen for that protein in this laboratory

Course of disease since November 1946 this patient has had 5 hospitalizations some for study and one for severe hepatitis probably homologous serum jaundice due to large amounts of plasma given her In the interim between admissions she worked as secretary at the hospital and had her meals from the research diet kitchen Her plasma protein remained low throughout the period of observation exceeding 6 Gm per 100 ml only once following the administration of large amounts of plasma There were two periods during which she had mild temperature elevations in the afternoon for which no cause could be found and which in one instance promptly receded following the administration of 50,000 units of penicillin every four hours for three days The second episode subsided spontaneously during it there was some swelling and reddening over the second joint of the third finger of the right hand accompanied by itching and interpreted by some observers as possibly a rheumatic manifestation by others as a urticarial phenomenon The latter hypothesis seemed more likely as there was no elevation of the sedimentation rate and as the lesion disappeared rapidly under pyribenzamine therapy In the absence of other signs the explanation suggested by some of these febrile and allergic episodes as manifestations of disseminated lupus erythematosus seemed unlikely The patient's course was otherwise uneventful except for the fact shown in table 2, that in spite of high protein intake her plasma protein concentration remained low

On May 2, 1947 the patient left for the South on a low salt high protein diet She returned on June

13 1947, with marked jaundice, anasarca and prostration. Liver functions were disturbed and her plasma protein level was at its lowest point (3.6 Gm per 100 ml). There were ascites and bilateral hydrothorax. Concentrated human plasma and albumin were given and a marked diuresis resulted. There was a dramatic increase of plasma volume and a fall of the extracellular fluid space as measured by thiocyanate. This change was so pronounced that pulmonary edema resulted and had to be treated actively (tourniquets on extremities, morphine). Following the re-establishment of her usual protein level of 5 Gm per 100 ml the patient improved rapidly while on a high protein diet and could be discharged on July 27, 1947. In October, 1947, all liver function tests measured gave normal results.

(Generation IV Fig. 1)

9 (MH 89947-SkI 390) This white boy aged 19 is the son of Case 3. He is a well-developed, healthy individual at present a member of a military academy where he has to undergo a rigid biannual physical examination. He has had chicken pox, mumps, whooping cough and measles. At the age of 7 he underwent a tonsillectomy. He had an injury to his right leg at the age of 12, which healed slowly. Other minor abrasions sustained in the course of sports healed at a normal rate.

Physical examination was negative except for the existence of a double vortex on the occiput.

Liver function tests were negative (thymol turbidity 0.15 ml bromsulfalein 2 per cent bilirubin 0.51 mg [0.29 indirect 0.22 direct 0.11 delayed direct] hippuric acid excretion 1.49 Gm cephalin flocculation negative).

A P S P excretion test was within normal limits.

10 A white boy aged 16, just entering puberty, brother of preceding patient. He had mumps and chicken pox but not measles. In 1939 he suffered an attack of intestinal influenza. Physical examination was negative except for prominent floating ribs.

11 This 13 year old boy had had measles and ascariasis, and has frequent colds. There was mild acne vulgaris. Physical examination was negative.

12 A well-developed white girl of 17, sister of the preceding patient. She had had chicken pox and measles but not mumps. There were no serious illnesses. Physical examination showed marked prominence of the floating ribs. Blood pressure was 125/75 and the oscillometric index in the arms was above 5.

13 This patient could not be reached.

14 This boy, aged 4, is the brother of Case 15 and the son of Case 7. He had a history of repeated colds and refractory infections of the toes. At the time of this examination he was apparently in good health. He had a double vortex pilorum and prominent floating ribs. Blood was taken for electrophoretic analysis. The blood group and type are shown in table 7.

15 This girl of 7 is the daughter of Case 7. She had none of the usual childhood diseases excepting repeated colds. Apparently she has always been in excellent health. Physical examination revealed a well-developed child, with prominent floating ribs and a double vortex pilorum. Blood was taken for electrophoretic analysis. The blood group and type are shown in table 7.

### ACKNOWLEDGEMENTS

We wish to acknowledge the courtesy of Dr. E. Shorr and Dr. E. A. Burkhardt who referred to us the first patient of this group. Several members of the staff of Memorial Cancer Center have helped in this study. The authors wish to thank Drs. E. McCabe and J. B. Trunnell for assistance in the clinical management of the patients; Dr. Aurelia Poror for performing the renal and adrenal function studies; Dr. N. F. Young who supervised laboratory procedures; Dr. H. J. Tagmann who performed the liver function tests assisted by Miss P. Nichols; Dr. C. G. Child III for performing the biopsies; Dr. S. Spitz, for the pathological interpretations and Dr. E. C. Reifstein, Jr. for advice in preparing the graphs and manuscript.

# PERIODIC (CYCLIC) NEUTROPENIA, AN ENTITY

## A COLLECTION OF SIXTEEN CASES

By HOBART A. REIMANN, M D and C. THOMAS DEBERARDINIS, M D

ATTENTION was called elsewhere<sup>1</sup> to several peculiar disorders which recur at remarkably regular intervals over many years without otherwise affecting the general health. It is uncertain if these different conditions, including cyclic neutropenia, are unrelated medical curiosities or, more likely, if they have a common cause and can be grouped together as periodic disease. Since the paper was published, a number of other reports of almost identical cases of cyclic neutropenia have been gathered from widely scattered sources, 16 in all. They are listed in approximate order of publication in table 1. A brief résumé of these cases and a detailed report of the study of a patient mentioned in the previous paper are presented here.

A case reported in 1910 by Leale<sup>2</sup> was the subject of two later studies by others. At the age of 3½ months a male infant had attacks of recurrent furunculosis and aphthous lesions in the mouth with fever as high as 40 C (104 F) every few weeks. Leukopenia with 1 per cent polymorphonuclear neutrophile cells was found on several occasions. Malaria was suspected. The case was regarded as recurrent agranulocytosis by Rutledge and his associates<sup>3</sup> in 1930 when the patient was 19. The attacks came at three week intervals with stomatitis, swelling of the cervical lymph nodes, malaise and fever. During the episodes the leukocytes numbered from 2,000 to 4,000 cells with from 0 to 16 per cent neutrophiles and the thrombocytes were diminished in number. The eosinophiles were always increased abnormally especially in an episode. The periodicity of some endocrinologic disturbance was suggested to account for the condition.

Further studies were reported by Thompson<sup>4</sup> in 1934, who tried to establish a relationship of the disorder to the neutropenia known to occur occasionally with the menstrual cycle. The patient by then had developed diabetes insipidus. Measurements of the excretion of gonadotrophic hormone and female sex hormone in the urine showed a fluctuation in rhythm with the neutropenic cycles. It was suggested that the patient, although a man, had a cyclic hormonal disturbance similar to the menstrual cycle. Communication with him in 1945 when he was 34 years old, shortly before death from pneumonia, revealed that the neutropenic cycle persisted at twenty-one day intervals but the constitutional symptoms had disappeared.

Sutton's<sup>5</sup> patient, described in 1911, at the age of 16, had had oral ulcers and fever recurrent every three weeks since the age of 3 months. A single normal leukocyte count was recorded during a free period. The case was again reported by Hoxie<sup>6</sup> two years later when the episodes recurred every fourteen to twenty days. At that time, pain and swelling of his left knee and occasionally of the hands oc-

curred during some of the episodes, at four to eight week intervals. At one occasion, 35 cc of clear fluid was aspirated from the knee. All of his teeth were removed as possible foci of infection with no effect on the episodes. No other leukocyte counts were recorded.

TABLE I — *Published Cases of Cyclic Neutropenia*

Author	Sex	Age at Onset	Age at last Examination	Interval in days	Fever	Other Remarks
1. Leale Rutledge Thompson	M	3½ mo	34	21	+	Psychic disturbance, eosinophilia at times
2. Sutton Hoxie	M	3 mo	18	14-21	+	Swelling of left knee at times every 4-8 weeks
3. Doan	F	1	35	21	0	Leukopenia less after splenectomy
4. Embleton	F	16	43	17-20	+	Series of episodes in 1919 1926 1936
5. Plum	M	2	12	21	+	
6. Imerslund	M	1	16	19-23	+	
7. Vahlquist	F	2 mo	4	21-22		Father had leukopenia of 3,000 cells but no other symptoms
8. Reznikoff	M	1	18	21	+	Abdominal pain. Concomitant cyclic diminution of 17 ketosteroids. After splenectomy leukopenia not so striking symptoms persist
9. Barling	F	12	32	21-28		Eosinophilia 1-10%. Episodes continued during pregnancy
10. Löffler	M	24	30	21	+	Eosinophilia arthralgia. Called Felty's Syndrome. No benefit after splenectomy
11. Reimann	M	5	21	20-25	0	Arthralgia
12. Alt	M	2	14	18-22		
13. Rulland	F	6 mo	8	21	+	Excretes abnormally large amounts of gonadotrophins
14. Fullerton	M	62	63	23-28	+	Splenectomy relieved symptoms but cyclic neutropenia occurs to lesser degree
15. Erf	F	52	56	21	+	Arthralgia splenectomy called Felty's Syndrome. Oral ulcers ceased after splenectomy. Still has cyclic low grade leukopenia
16. Owren	M	18	23	14-21	+	No benefit after splenectomy

Doan's<sup>7</sup> patient, a woman of 18, had had neutropenia, dermal and oral ulcers every eighteen to twenty-one days since the age of 1. The patient and her mother had hemolytic icterus. During the episodes there was absolute neutropenia and a total leukocyte count of 2,000 to 3,000, of which 50 per cent were monocytes. After splenectomy the leukocytes did not fall below 5,000 per cubic millimeter but the number of granulocytes continued to fluctuate in the usual rhythm but to a lesser extent.

Embleton's<sup>8</sup> patient, a woman of 43, had ulcers in her mouth, malaise and fever of 38.9 C (101 F) every seventeen to twenty days for several months in 1919, in 1926 and when reported in 1936. In the intervals between the episodes she felt well and studies of her blood showed no abnormality. During the episodes, the leukocyte count fell to 3,000 per cu mm and the neutrophil cells disappeared. The erythrocytes showed vacuolization, poikilocytosis and many were microcytes, and the platelets 'became exceedingly numerous'. To account for the cycles, the author raised the question of a response to the life cycle of some parasite.

Plum's<sup>9</sup> patient, a youth of 12, had had recurrences of neutropenia at three week intervals since the age of 2.

A patient, aged 16, studied by Imlerslund<sup>10</sup> had had recurrences of shivering, malaise, anorexia, fever of 41 C (105 F), and swollen cervical lymph nodes every three weeks since the age of 14 months. During observation, the number of leukocytes did not fall greatly during the episodes, but the neutrophil cells diminished to 1 to 6 per cent. The sternal marrow during an episode showed a shift to the left, hyperplastic reticulum, an arrest of the development of neutrophil cells at the myelocyte-promyelocyte stage, and an increased number of monocytes compatible with the picture seen in malignant neutropenia. Injection of epinephrine hydrochloride during the neutropenic period caused the lymphocytes to increase, not the neutrophils. While an endocrinologic basis was suspected as an underlying cause of the cyclicity of the attacks, there was no clinical evidence of endocrine dysfunction and a normal amount of folliculin was excreted.

In Vahlquist's<sup>11</sup> patient, a girl of 4, episodes of cutaneous abscesses, fever and cervical lymphadenopathy began at the age of 2½ months. Oral ulcers are not mentioned. The recurrences appeared at fifteen to forty-five day cycles, but the basic rhythm was twenty-one to twenty-three days. Mild asthma occurred at times. Monocytosis compensated for extreme neutropenia. The total leukocyte count often fell to 2,900 in the episodes. The bone marrow obtained during an attack suggested myeloblastic leukemia rather than agranulocytosis. The leukocytes of the father numbered 3100 and 4600 on two occasions, but no leukopenic rhythmicity was demonstrated.

Reznikoff's<sup>12</sup> patient, a youth of 18, had had periodic attacks of fever, canker sores and abdominal pain since infancy. The episodes occurred every twenty-one days and lasted ten days, of which four were usually spent in bed. The cervical and axillary lymph nodes and the spleen became swollen during the attacks. The leukocytes, normal during the free intervals, dropped to 3,000 and 2,000 cells per cu mm and the neutrophil cells to 2 to 15 per cent of the total. Between attacks, the leukocyte count of the marrow varied between 19,000 and 56,000, of which 13,500 to 37,500 were neutrophil cells or their precursors. At the low point the count fell to 1,800 with only 340 neutrophilic elements. Over a three month period the 17-ketosteroid excretion showed a diminution after the onset of the episodes. Other studies including those to determine an allergic disturbance were unrevealing. After splenectomy the only changes noted were that the total leukocyte count did not fall so far as before and the abdominal pains were not so severe.

The case briefly reported by Barling<sup>13</sup> occurred in a woman of 37, who since the

age of 12 had had ulcers in the mouth at intervals of three to four weeks. The ulcers were worse during pregnancy in 1944. Examination of the blood during the free periods showed no abnormalities except for a persistent slightly low percentage of neutrophile cells. During the episodes the total count fell to 1300 at times and the percentage of neutrophilic cells to 15.

The patient studied by Löffler and Maier<sup>14</sup> was regarded as having Felty's syndrome with cyclic agranulocytosis because of anemia, arthralgia, lymph node swelling and granulocytopenia. He was 30 years old. After an attack of pneumonia six years before in 1942, leukopenia and monocytosis had been detected. The spleen and lymph nodes enlarged slightly and stomatitis was noted. He was well, however, until seven months later when polyarthritis lasting three days occurred. The leukocytes numbered 4,600 with 15 per cent neutrophile cells. In the next fourteen months there occurred periodic attacks of polyarthritis with fever at regular twenty-one day intervals. The neutrophiles began to diminish to almost complete agranulocytosis five days before fever appeared. At the time, the cells of the marrow showed a predominant promyelocytic picture. Splenectomy brought no benefit. Examination of the spleen showed chronic inflammatory hyperplasia with eosinophilia.

During the course of observation, aortic insufficiency, presumably from endocarditis, developed in 1943 and shortly after, an attack of pneumonia and empyema. His tonsils and all of his teeth were removed as presumed foci of infection, with no beneficial effect.

Dr. Howard Alt, of Chicago, kindly supplied the following data of his patient. A youth of 18 had had attacks of gingivitis and oral ulcers since the age of 2. He was studied over a five months period in 1941-42 during which six episodes with almost complete neutropenia were observed. They came at intervals of eighteen to twenty-two days. The monocytes increased to 30 to 36 per cent during the periods and the total leukocyte count was 4,000. In the free periods the neutrophiles comprised from 30 to 50 per cent of the leukocytes.

Dr. C. F. Rolland, of Edinburgh, informed us of his patient, a girl aged 7½, who has had febrile attacks with oral ulcers at intervals of about twenty-one days since 6 months of age. There was neutropenia at all times which became absolute during the episodes when monocytosis occurred. An endocrinologic basis of the disorder was suspected and measurements showed the excretion of larger amounts of gonadotrophic hormones than normal.

A woman of 56, studied by Erf,<sup>15</sup> had weakness, fatigue, fever and oral ulcers at three week intervals for over two years. Her menopause occurred at the age of 50. She was studied at this hospital preparatory to splenectomy. There were ulcers on the mucosa of the tongue and cheeks, and the spleen was palpable. Fever was present for two days. The leukocytes numbered between 1,000 and 2,000 with 2 to 4 per cent polymorphonuclear cells. After splenectomy the symptoms disappeared but the leukocytes (counted elsewhere) at times numbered less than 5,000 with 1 to 25 per cent neutrophile cells.

According to Fullerton and Duguid,<sup>16</sup> the disorder began in their male patient at the age of 62 and recurred at intervals of twenty-three to twenty-eight days.

The episodes were characterized by sore throat, conjunctivitis, ischio-rectal infection and oral ulcers. Between attacks the neutrophils rarely reached the normal number. The fall in the number of neutrophils in an episode preceded the rise of temperature and they usually disappeared for four or five days. Studies of the marrow, as in our patient, indicated a periodic failure of the production of neutrophil cells as the cause of their disappearance. No fluctuation in the excretion of 17 ketosteroids was demonstrable. Sulfonamide compounds, penicillin, antihistaminic drugs and pyridoxine had no effect on the condition. After splenectomy, distressing symptoms no longer occurred, but as in Doan's and Reznikoff's patients, cycles of neutropenia recurred in lesser degree of severity.

Owren's patient,<sup>17</sup> a man of 23, had had episodes every two to three weeks since the age of 18, often with complete agranulocytosis. They lasted a week,

FIG. 1.—Cyclic neutropenia, oral ulcers, headache and malaise lasting eight to ten days and recurring every twenty-three to twenty-six days. The diminution of the neutrophil cells precedes the clinical symptoms represented by the shaded bars to indicate their gradual increase and decrease in intensity.

were accompanied by fever, oral ulceration, and at times by conjunctivitis, ulceration of the skin of the face, perineum and extremities. Studies of the marrow showed disappearance of the mature granulocytes during an episode and their rapid reappearance before the neutrophils returned to the peripheral blood. Between the attacks, the granulocytes in the blood seldom exceeded 1000 per cubic millimeter. Tonsillectomy and splenectomy had no effect on the condition and the patient died later from pneumonia.

#### CASE REPORT

**L. F.** a man aged 23, had been studied at a hospital when 5 years of age for painful swollen joints, general aching, enlarged cervical lymph nodes and sores in his mouth. A diagnosis of rheumatic fever was made. The disorder recurred a year later and after that two or three times a year. He was well otherwise.

In 1944, at the age of 18, he entered the Army. In 1945 he was treated at a military hospital for acute tonsillitis, but no laboratory studies were made. In June 1945, the characteristic three-week cyclic attacks of fever, headache, neutropenia, malaise, sore throat, swelling of the cervical lymph nodes, arthralgia and oral ulcers began. Therapy with sulfadiazine and penicillin had no effect on the condition.

He was discharged from the Army and entered the Jefferson Hospital for study as a patient of Dr. L. M. Tocantins in December 1945. He was observed for nine months. A portion of a chart showing the fluctuation of the number of neutrophil cells in relation to the oral ulcers is shown in figure 1. The

episodes recurred in twenty to twenty-six day cycles. An episode began with a gradual diminution in the number of neutrophile cells for three to four days when they occasionally disappeared from the blood. During this period the signs and symptoms began at times accompanied with fever of 37.4 C (100 F). He usually remained ambulatory but in some attacks had to go to bed. Physical examination revealed a healthy looking well-developed man with a small ulcer in his tongue, a reddened pharynx and slightly swollen anterior cervical lymph nodes. The edge of the tongue was scalloped with scars from previous ulcers. The temperature was normal and the liver and spleen were not palpable.

The erythrocytes numbered 4,100,000, the hemoglobin 14 Gm. There were 3,700 leukocytes of which 15 per cent were neutrophiles, 39 per cent lymphocytes, 43 per cent monocytes and 3 per cent eosinophile cells. The sedimentation rate was 21 mm in 60 minutes, the hematocrit 41 per cent, the bleeding time 30 seconds. The erythrocytes were normally fragile to hypotonic salt solutions. The venous clotting time and clot retraction were normal. The serologic tests for syphilis gave negative results. The Van den Bergh test gave a negative direct reaction and the indirect reading was 0.8 mg. A leukocyte count made between 2 episodes showed 5,000 cells of which 22 per cent were neutrophiles. There was a constant compensatory increase in the number of monocytes. The other cellular elements remained fairly unchanged in number.

Repeated studies of the sternal marrow showed granulocytic hypoplasia during the episodes. Between times these elements were normal. Changes in the marrow always preceded those in the blood. All of the other usual laboratory studies and roentgenograms gave negative results. Many measurements of the basal metabolic rate gave normal results during and between episodes. No cyclic changes were noted in measurements of the CO<sub>2</sub> combining power of the blood over a period of thirty days. The excretion of urinary gonadotrophins, estrogens and 17 ketosteroids were measured thirteen times without evidence of synchronous fluctuation with the cycles of neutropenia. On all occasions the amounts were within normal limits.

A number of special tests were performed during the episodes and in the free periods. In an interim period 25 mg. of adrenocorticotrophic hormone was injected intramuscularly and the leukocytes counted at hourly intervals. A normal response occurred. The number of leukocytes remained constant but the percentage of neutrophile cells rose from 59 to 80 by the fourth hour, the highest ever noted in this person with a corresponding diminution of monocytes. The total number of eosinophiles fell from 166 to 53 per cu. mm. The test was repeated during an episode of neutropenia. The eosinophile cells again were diminished by 50 per cent but the leukocyte count fell from 4,000 to 2,000 with a further decrease in the neutrophile cells and an increase in lymphocytes and monocytes.

During another interim period the intravenous injection of 0.1 unit per kilogram of crystallin insulin caused a slight increase in the number of leukocytes but with no increase in the number of neutrophile cells.

During two periods of neutropenia 1 cc. of 1:1000 solution of epinephrine hydrochloride was injected subcutaneously. Leukocyte counts made at five minute intervals thereafter revealed no changes in the number of component cells on either occasion. Either too few cells were available for release into the blood or they failed to be released.

Brewer's yeast in amounts of 25 tablets daily together with the intramuscular injection of 15 units of liver extract three times a week had no effect on the cycles. Folic acid in doses of 100 mg. orally daily or 20 mg. given intramuscularly, yellow bone marrow in amounts of 1 cc. intramuscularly every other day and pyridoxine in doses of 200 mg. intravenously daily given successively over adequate periods all had no effect on the episodes. Testosterone propionate 50 mg. intramuscularly twice a week given over a period of three weeks was likewise ineffectual.

## DISCUSSION

Two striking features stand out in the 16 cases observed. One is the similarity of all cases sufficient to warrant establishment of the disorder as an entity, the other is the remarkably uniform three week regularity of the cycles. In 9 instances the disorder began in infancy and in 2 at ages 5 and 12. Two began, or became evident, at ages 56 and 62. In most instances the recurrences when once established,

persisted, but in one,<sup>8</sup> the episodes recurred in three distinct periods. Oral ulcers suspected as the cause by some, probably represent only the secondary effects of other disturbances as in the better known forms of neutropenia or agranulocytosis. Fever noted in most patients may be caused by the mild infection incident to the ulcers, as suggested also by cervical lymphadenopathy. It is noteworthy, however, that in only 2 patients,<sup>14, 16</sup> were severe infections recorded, in contrast with their frequency in other forms of severe neutropenia. Either the cyclic neutropenic stage does not last long enough to allow serious infection to occur or neutrophil cells are not the most important factor in the defense against infection. Arthralgia is recorded in 4 cases, prominent enough in 2<sup>14, 16</sup> to suggest a diagnosis of Felty's syndrome. Two patients<sup>4, 17</sup> died from pneumonia.

Ten of the 16 patients were males. The frequency with which the disorder begins in infancy suggests a congenital aspect. In one instance<sup>11</sup> a genetic influence is suggested by the discovery of leukopenia without other signs or symptoms in the patient's father.

It is highly probable that the disorder is not so rare as it seems to be from the few cases thus far reported. They may represent only the severest instances of an unrecognized cyclic condition which could be discovered only if the leukocytes were counted frequently in many persons over long periods, particularly in the relatives of patients with the disorder. That other cases, unrecognized as such, exist is suggested in queries addressed to the editor of a medical journal.<sup>18</sup> In one instance, a man aged 21 had recurrent oral ulcers lasting seven to ten days at intervals of two weeks to three months for three years. In another, a woman, aged 27, had recurrent episodes of sore throat at intervals of two to four times a month for many years. A relation of cyclic neutropenia to other periodic disorders such as periodic fever, benign paroxysmal peritonitis and intermittent arthralgia as suggested elsewhere<sup>1</sup> is likely. The length of the cycles is about the same in each, and certain clinical features such as leukopenia, fever, arthralgia and abdominal pain are present at times in all four conditions. Demmer's<sup>19</sup> case of a man aged 61, who had recurrences of purpura and thrombopenia at twenty-eight day intervals for six years, may also fall into the group.

The cause of the disorder and why the cycles are of three weeks' duration in each case are obscure. To some observers, the rhythmicity suggests a hormonal influence, yet there is no relationship of the episodes to the menstrual cycle, they occur in both sexes, they may commence in infancy or after the menopause, and except for diabetes insipidus in Thompson's patient, no other endocrinologic disturbance is evident in any of the 16 cases. Synchronous cyclic fluctuation of measurable hormones, even if demonstrable, may be the result of the disorder, not a cause. Hormonal therapy failed to influence the cycles in our patient and in those of others. The attacks persisted during pregnancy in one instance.<sup>12</sup>

The cycles are not likely to be connected with a normal periodic renewal or formation of neutrophil cells since the change in all cases is that of diminution in number. The neutropenia probably results from a decrease in the rate of formation as suggested by changes in the bone marrow preceding those in the blood. Eosinophilia, noted in 3<sup>4, 13, 14</sup> may represent a compensatory increase of the

cells or some allergic reaction. Asthma, however, is recorded in only one instance<sup>11</sup> and antihistaminic drugs had no effect on the cycles.<sup>16</sup> It is most unlikely that any infection would cause changes to occur so regularly and uniformly over periods of years.

Of the various forms of therapy thus far applied, only one caused a significant change. In 4 cases,<sup>7, 1\*, 16, 18</sup> splenectomy induced an amelioration of the symptoms or a less striking diminution of the neutrophils, or both, but in two cases<sup>14, 17</sup> no benefit followed. In Thompson's case,<sup>4</sup> symptoms disappeared spontaneously but the neutropenic cycles persisted.

### SUMMARY

Sixteen cases of an entity, periodic neutropenia, have been collected. They are characterized by remarkable clinical uniformity and regular recurrences of neutropenia at three week intervals. The entity may be a variant of a larger group of periodic conditions. The cause is unknown.

## LIVER EXTRACT REFRACTORY MEGALOBlastic ANEMIA

By JOHN F. MUELLER, M.D., V. R. HAWKINS, R.N., AND RICHARD W. VILTER, M.D.

RECENTLY we have had the opportunity to study a patient with a macrocytic anemia and megaloblastic bone marrow, who was refractory to parenteral therapy with vitamin B<sub>12</sub> and refined liver extract, but who responded to folic acid. This type of macrocytic anemia is rare, particularly in this country. Observations made in this case support the concept of a chemical interrelationship between liver extract, vitamin B<sub>12</sub> and folic acid and contribute evidence favoring the existence of another factor necessary for normal erythrocyte maturation.

### CASE REPORT

L. R., a 52-year-old former railroad yard worker was referred to our out-patient department on 9-17-48 by a private physician for the treatment of pernicious anemia with vitamin B<sub>12</sub>. The patient gave a history of about six months' duration of progressive weakness, shortness of breath on exertion, several attacks of syncope and sore tongue. The latter prevented the patient from eating most solid foods. Increasing drowsiness, failing vision and increased sensitivity to cold were other subjective complaints. There was no history of diarrhea at any time. His diet prior to this illness had probably been adequate but he admitted a rather heavy intake of alcohol over a period of years. His family had noted a definite change in his personality manifested by extreme irritability and ill humor.

Physical examination revealed a thin, pale white man who appeared chronically ill. He cooperated well. His sclerae were not icteric but his tongue was atrophic and reddened along the lateral margins. His chest, heart and abdomen were normal. All the deep tendon reflexes were extremely hyperactive but there was no clonus nor pathologic reflexes. The Romberg test was normal. Perception of vibration was reduced in the lower extremities, more over the right ankle than the left. Position sense was intact in the toes. There were no other sensory abnormalities.

Laboratory examination revealed: erythrocyte count 1,620,000 per cu. mm., hemoglobin 6.8 Gm. per cent, hematocrit 20 per cent, reticulocytes 1.9 per cent, M.C.V. 123 cu. microns, M.C.H. 4.2 micrograms, M.C.H.C. 34 per cent, white blood cell count 3550 per cu. mm. with a normal differential count, and platelets were 181,440 per cu. mm. A gastric analysis done by the private physician revealed a histamine fast achlorhydria. Urinalysis Kahn, E.C.G., barium studies of the upper and lower gastrointestinal tract, x-ray of the chest and brucella agglutination were normal. A needle biopsy of the sternal bone marrow revealed maturation arrest in the erythrocyte series at the megaloblastic and early erythroblastic stages of development. Bizarre metamyelocytes and macrocytic polychromatophilic normoblasts were abundant. (See table 1.)

We concurred in the diagnosis of pernicious anemia and administered 8 micrograms of vitamin B<sub>12</sub> parenterally (we have obtained maximal reticulocyte responses with only 4 micrograms of vitamin B<sub>12</sub>). Thereafter reticulocytes were counted each day. Erythrocytes and hemoglobin were determined every third day. Reticulocytosis did not occur. By the fourth day after therapy the patient was complaining bitterly about the soreness of his tongue and small congested papillae were visible on the smooth lateral margins. He was placed on multivitamin tablets without relief. Neurologic examination did not change. By 9-27-48, ten days after the initial dose of vitamin B<sub>12</sub>, the erythrocyte count had dropped to 1,185,000 per cu. mm., the hemoglobin to 6 Gm. per cent and the hematocrit to 17 per cent. He was then given 8 micrograms of vitamin B<sub>12</sub> on each of three successive days. Although there seemed to be a little tempo-

From the Department of Internal Medicine, University of Cincinnati, Cincinnati, Ohio.  
These investigations were aided by grants from Merck and Co. Inc., Rahway, New Jersey and the Robert Gould Research Foundation, Inc. We wish to thank Merck and Co. Inc. for their liberal supply of vitamin B<sub>12</sub> and Lederle Laboratories, Inc. for the folic acid.

rary subjective improvement the patient continued on a downhill course and was admitted to the Cincinnati General Hospital on October 2, 1948 for further study and treatment

FIG. 1—THE HEMATOLOGIC COURSE OF A PATIENT WITH REFRACTORY MEGALOBlastic ANEMIA

TABLE 1—Bone Marrow Counts on a Patient with Liver Extract Refractory Megaloblastic Anemia

Date	9-17-48 On Admission	10-3-48 After Vitamin B <sub>12</sub>	10-13-48 After Liver Extract	10-26-48 After Folic Acid
Polymorphonuclear neutrophile	48	37	38.5	57
Metamyelocyte	14.5	33.5	29.5	24
Myelocyte C	8.5	3	8.5	2
Myelocyte B	3	3.5	5	0.5
Myelocyte A	1	3	1	0
Myeloblast	0	0.5	0	0
Lymphocyte	12.5	10	12	10
Young lymphocyte	0	0	0	0
Monocyte	0.5	0	0.5	1
Young monocyte	0.5	0	0	0.5
Eosinophile	2	2	2	0.5
Eosinophilic myelocyte	1.5	2	1	2.5
Basophile	0	0	0.5	0
Basophilic myelocyte	0.5	0	0	0
Plasma cell	4.5	1.5	1.5	2
Clasmatocyte	0	0	0	0
Primitive cell	3	4	0	0
Megaloblast	4	7	1.5	0
Early erythroblast	10	13	18.5	1.5
Late erythroblast	19.5	10.5	33	14
Normoblast	12.5	45	24	46
Myeloid Erythroid ratio	2.1	4.3	5.4	5.3

On his admission the physical examination gave essentially the same findings except for a small papule on the margin of his tongue which later broke down to form a small ulceration. The neurologic examination was unchanged. The erythrocyte count was 1 050 000 per cu mm, hemoglobin 5 Gm per cent, hematocrit 16 per cent, white blood cells 1950 per cu mm, reticulocytes 1 per cent. Liver function tests were normal except for retention of 8.5 per cent of injected bromsulphthalein (5 mg/Kilo) after forty five minutes. The total serum bilirubin was 0.4 mg per cent. An analysis done on a 24 hour stool specimen revealed a total fat content of 16 per cent by dry weight, 7.9 Gm total fat in twenty four hours of which 5 Gm were fatty acids. Oral glucose tolerance test revealed slow submaximal absorption but not a flat curve such as occurs in sprue. Bone marrow aspiration showed no change from the previous megaloblastic maturation arrest. On October 3, 1948, the patient was given 30 units of refined liver extract, Lederle, an amount which is roughly equivalent to the amount of vitamin B<sub>12</sub> injected previously. Again there was no reticulocyte response and the erythrocyte count continued to fall, so that by 10-13-48 ten days after the liver extract the erythrocytes numbered 840 000 per cu mm and the hemoglobin 4 Gm/100 cc. Bone marrow examination again revealed the same maturation arrest. Although the patient was unchanged clinically, he was given 500 cc of whole blood at this point in order to avoid the possibility that retransfusion might be necessary during the next therapeutic trial period.

On October 16, 1948, the patient was started on a ten day course of folic acid, 7.5 mg each day intramuscularly, so that the total dose of 75 mg would be roughly comparable to 30 units of refined liver extract. A reticulocyte response occurred and reached its maximum of 16.9 per cent on the fifth day. Clinical improvement was striking. The erythrocyte count increased slowly but by 10-29-48 when he was discharged it had risen to 2,410 000 cells per cu mm and the hemoglobin was 9.4 Gm per cent. Subsequently his blood counts have continued to rise toward normal. The bone marrow reverted to a normoblastic phase of maturation. The neurologic signs did not change appreciably.

During two days preceding folic acid therapy and the three days following the first dose of folic acid 24 hour urine samples were collected and their respective contents of folic acid measured through the courtesy of Dr. A. L. Franklin of Lederle Laboratories. The results were as follows:

Date	Urine Vol. ml	Therapy mg folic acid	Micrograms folic acid/ml	% excretion
10-8-48	750	—	0012	—
10-9-48	750	—	0015	—
10-17-48	800	7.5	3.0	32
10-18-48	425	7.5	6.0	33
10-19-48	750	7.5	5.0	49

These excretion values are within the range excreted by normal subjects.

A gastric analysis with histamine stimulation repeated in December 1948 revealed

Specimen	Free acid	Combined acid	Total acid
Pre histamine	13	5	18
Post histamine	19	11	30

### DISCUSSION

In 1936, Israels and Wilkinson<sup>1</sup> described a type of macrocytic anemia similar morphologically to pernicious anemia, but lacking the clinical manifestations of achylia gastrica, neural involvement, jaundice and glossitis. The bone marrow was megaloblastic, but the anemia responded poorly or not at all to the usual parenteral liver therapy. The authors suggested that achrestic anemia might be a suitable

name since they felt that liver extract was not utilized properly. In 1937, Wills, Clutterbuck and Evans<sup>2</sup> reported that experimentally induced macrocytic anemia in monkeys failed to respond to refined liver extracts such as Anahaemin but responded quite well to crude extracts such as Campolon. This was followed in 1938 by clinical reports by Napier<sup>3</sup> et al. and Wills and Evans<sup>4</sup> of cases of tropical macrocytic anemia which failed to respond to Anahaemin, but subsequently responded to Campolon. It was from this work that the term "Wills factor" appeared, to designate an unknown active factor in crude liver. Numerous reports of similar experience followed from other countries.<sup>5-7</sup>

In England, Davidson, Davis and Innes<sup>8</sup> in 1943, later Davidson and Girwood<sup>9</sup> in 1946 and Davidson<sup>10</sup> in 1948 described a total of 25 cases which they called "idiopathic refractory megaloblastic anemia." All were refractory to refined liver extract. Nine of these cases received in addition, iron, ascorbic acid and transfusions and improved slowly. Twelve patients received proteolyzed liver, a papain digest of whole liver administered orally, with a prompt response in 8 and a moderate response in the remaining 4. The daily dose of the proteolyzed liver was shown to contain only 0.4 mg. of folic acid. The authors therefore felt that there is still another unknown hematinic principle in the proteolyzed liver. The remaining 5 cases were given folic acid with a prompt, but submaximal response. They required proteolyzed liver to attain normal erythrocyte values. These authors also reported 34 other cases of refractory megaloblastic anemia which were associated with pregnancy, the puerperium or the sprue syndrome.

In 1946, Watson and Castle<sup>11</sup> reported 4 cases of nutritional macrocytic anemia which were refractory to parenteral liver therapy. These patients had in common an inadequate diet, free hydrochloric acid in the gastric contents, absent neural manifestations and normal lingual papillae. Bone marrow morphology was not reported. In 2 of the patients, the anemia occurred during pregnancy. The first 2 patients responded to liquid extract of liver (Valentine). The third responded to the oral administration of a suspension-solution of powdered liver extract (Lilly) and the fourth responded to the daily intravenous injection of 20 cc. of the supernatant of this special liver preparation. The fourth patient received 13 mg. of L. casei factor daily for 10 days along with other members of the vitamin B complex without benefit prior to the administration of liver extract. These authors concluded that the crude liver preparations given in large doses contained some hematoopoietic factor not present in the more refined liver extracts. They were willing to designate this substance the "Wills factor," and did not believe that it was folic acid.

Waldenström<sup>12</sup> in 1947 reported 4 cases of refractory macrocytic anemia, 3 of which responded to folic acid given by mouth. Two of these had responded previously to liver and then had become refractory. The one case that did not respond to folic acid was classed as idiopathic steatorrhea.

Recently Bethell and co-workers<sup>13</sup> reported briefly a case of puerperal macrocytic anemia in a 19 year old mother who had a megaloblastic marrow, free acid in the gastric juice, and glossitis. This anemia did not respond to a total of 10 gamma

of  $B_{12}$  intramuscularly over a ten day period, but responded to 10 mg of folic acid by mouth per day

The patient described in our report differs in certain minor clinical respects from most of the other cases of liver extract refractory macrocytic anemia. Objective neurologic signs were present which were probably manifestations of mild peripheral neuritis and cerebral atrophy induced by alcohol. The patient also had an acute glossitis which was unrelieved by vitamin  $B_{12}$  and refined liver extract, but responded to folic acid. In these respects he was similar to several patients with extrinsic factor deficiency reported by Moore, Vilter, Minnich and Spies.<sup>14</sup> However, failure to respond to purified liver extract makes such an etiology untenable. Pernicious anemia is eliminated by the return of free hydrochloric acid after treatment, and sprue seems unlikely without evidence of diarrhea or steatorrhea. There had been no gastro-enteric surgery and his gastro-enteric tract was normal when visualized with barium. By elimination he must be classified as liver extract refractory macrocytic anemia due to unknown causes. The hematopoietic effect of folic acid is similar to results reported by European clinics.

It seems probable that persons said to have achrestic anemia, Wills factor deficiency anemia and many instances of megaloblastic anemia of infancy and pernicious anemia of pregnancy, are all due to the same fundamental chemical deficiency.

The evidence in our case fails to demonstrate a primary etiologic role for folic acid deficiency because the excretion of this substance after parenteral injection was within the range expected in normal persons. For this same reason, a defect in the folic acid conjugase system is unlikely. Therefore, one must assume the existence of another factor, which acts in conjunction with folic acid in the process of erythrocyte maturation. The identity of this factor is unknown but it must be present in crude liver preparations such as proteolyzed liver. If this is true, folic acid in relatively large doses can overcome a deficiency of this factor by a mass action effect, a mechanism which may also explain its hematopoietic action in pernicious anemia where it overcomes a chemical deficiency, probably of vitamin  $B_{12}$ , conditioned by lack of intrinsic factor in the gastric juice.

Studies on the growth requirements of bacteria link folic acid<sup>15</sup> to thymine and vitamin  $B_{12}$ <sup>16</sup> to thymidine synthesis and suggest that these factors are intimately related to purine and pyrimidine metabolism. The inhibition of folic acid antagonists on bacterial growth and the ability of purines and pyrimidines to overcome or circumvent the inhibition<sup>17</sup> demonstrate these interrelationships also. The hematopoietic effect of large amounts of a pyrimidine, thymine, in human pernicious anemia, nutritional macrocytic anemia and sprue suggests that these concepts may be applicable to human nutrition.<sup>18</sup> The possibility that one of the points of breakdown of hematopoiesis in pernicious anemia may be the failure to convert thymine to thymidine has been suggested before.<sup>19</sup> It is likely that chemical chain reactions leading to the formation of nucleo-protein from amino acids are catalyzed by these factors derived from liver, and that folic acid and the unknown factor are essential for one step and vitamin  $B_{12}$  for a closely related one. Under such circumstances any one of these factors given in large doses, could overcome temporarily defi-

ciencies of the others, and thymine, one of the substrates of the reaction, would be effective in very large doses. Such a theory offers an explanation for the effect of folic acid in the patient described in this report and helps to explain many puzzling problems which have arisen in the field of macrocytic anemias.

### SUMMARY AND CONCLUSIONS

1 The patient described in this report had macrocytic anemia, megaloblastic maturation arrest in the bone marrow, glossitis, hyper-reflexia and diminished vibration perception in the feet. None of these abnormalities was improved by liver extract or vitamin B<sub>12</sub> but all responded rapidly to folic acid except the neurologic signs.

2 This patient appears to have had a megaloblastic anemia which has been described in European clinics under the names achrestic anemia and refractory megaloblastic anemia. It appears to be similar to Wills factor deficiency anemia and some cases of pernicious anemia of pregnancy.

3 This patient did not appear to have a primary deficiency of folic acid since the excretion of this substance in the urine was within normal limits. A deficiency of an unknown factor probably equivalent to the Wills factor is suggested.

4 It seems likely that folic acid induced a remission in this case by a mass action effect. The possible relationship of folic acid, vitamin B<sub>12</sub>, the unknown factor and liver extract to nucleo-protein synthesis is discussed.

### ADDENDUM

Since the completion of this paper, the patient herein reported, has been readmitted in hematologic relapse. He had received no interim treatment due to his failure to report back to us. During his second stay in the hospital he was treated with thymine, 13.2 Gm daily for ten days. Reticulocytosis of 10 per cent occurred and a rise in erythrocytes and hemoglobin is in progress. This hematologic response is consistent with the theory outlined above.

### ACKNOWLEDGMENT

We wish to thank Doctor Charles Foertmeyer for referring this patient to us for the clinical study used in this report.

## A NOTE ON THE EFFECTIVENESS OF VITAMIN B<sub>12</sub> IN THE TREATMENT OF TROPICAL SPRUE IN RELAPSE

By RAMON M. SUAREZ, M.D., TOM D. SPIES, M.D., F. HERNANDEZ MORALES, M.D., AND ENRIQUE PEREZ, M.D.

*With the technical assistance of Miss CLEMENCIA BENITEZ-GAUTIER*

A SHORT time ago, vitamin B<sub>12</sub> was isolated<sup>1-5</sup> and shown to have a profound effect on blood regeneration in persons with pernicious anemia, nutritional macrocytic anemia, tropical sprue and nontropical sprue.<sup>6-9</sup> It also was found to be beneficial in relieving the acute and subacute combined degeneration of the spinal cord which so often is associated with pernicious anemia.<sup>10-13</sup> However, until very recently the amounts of vitamin B<sub>12</sub> available have been so small that investigators have not had sufficient amounts to treat patients fully. We decided to use part of our small supply of this material to make an intensive study of 3 patients with tropical sprue and to treat them over a considerable period of time, the thought being that it would probably take much larger amounts of vitamin B<sub>12</sub> to produce full remission than might be apparent from the dramatic hemopoietic response produced by minute doses. These 3 patients, studied in the hospital under controlled conditions, indicate that such is the case. The three following case histories of these patients illustrate their clinical and hemopoietic response to vitamin B<sub>12</sub> administered at fairly frequent intervals over a period of from 138 to 160 days.

These patients were selected for study by the following criteria: (1) The patient must have macrocytic anemia as determined by Wintrobe indices. (2) The bone marrow must show the typical megaloblastic type of maturation arrest seen in macrocytic deficiency anemias. (3) The erythrocyte counts must be below 2.5 million. (4) The patient must be untreated, or must not have been treated recently enough to interfere in any way with the evaluation of vitamin B<sub>12</sub> as a therapeutic agent. (5) He must have persistently low reticulocyte counts during the preliminary period of observation. (6) He must have alimentary tract symptoms consistent with the diagnosis of tropical sprue.

Pipets certified by the United States Bureau of Standards were used for the red cell counts. The hemoglobin content was determined by means of the Photovolt photoelectric hemoglobinometer, calibrated so that 14.5 grams was equivalent to 100 per cent. The reticulocytes were counted in dry preparations of brilliant cresyl blue counterstained with Wright's stain. Platelets were enumerated in the counting chamber used for red blood cells by means of a fresh solution of sodium citrate.

Sternal bone marrow was obtained by aspiration prior to treatment and again near the peak of reticulocytosis.

From the School of Tropical Medicine of Puerto Rico and Northwestern University Department of Nutrition and Metabolism.

This study was aided by a grant from the Martha Leland Sherwin Fund. The vitamin B<sub>12</sub> used in this study was supplied by Dr. Augustus Gibson, Merck and Company, Rahway, New Jersey.

Gastric analyses were performed in each case

On admission the patients were given the preliminary sprue diet previously described<sup>14</sup> and were maintained on this diet throughout the period of study. After the baseline studies were completed, the three patients selected were treated with vitamin B<sub>12</sub> at intervals of from 138 to 160 days

*Case 1* D.G., a 28 year old Puerto Rican woman was admitted to the hospital in May 1948 complaining of loss of appetite, soreness of the tongue and diarrhea characterized by frequent light-colored foamy stools

Family history and past history Irrelevant

Present illness The patient was in good health until after the birth of a normal child four years prior to her admission. At this time she lost her appetite, had occasional nausea and vomiting and developed diarrhea consisting of from six to eight soft, bulky, foamy, foul smelling, light yellow stools daily. During the following eight months she grew progressively weaker and lost 17 pounds in weight. At the end of this time she came to the Out-Patient Department of the hospital where a diagnosis of tropical sprue was made. She was given 8 cc. of crude liver extract three times a week. Following this therapy she improved only slightly and then very slowly. She became discouraged and stopped coming for treatment. By April 1948 she again developed loss of appetite, soreness of the tongue and severe foamy diarrhea. Within a month she was so weak she came to the hospital and was admitted for treatment.

Physical examination showed a poorly-developed, undernourished young woman who was obviously and chronically ill. The mucous membranes were very pale. The tongue was smooth and red, especially at the tip and edges.

Gastric analysis showed free hydrochloric acid in the gastric contents. The initial blood values were: red blood cells 2.41 million, hemoglobin 7.6 grams (48 per cent), reticulocytes 1.0 per cent, as can be seen in figure 1. She was given a total of 210 micrograms of vitamin B<sub>12</sub> in nine injections in a period of 147 days. Fifteen days after the last injection her blood values were: red blood cells 4.12 million, hemoglobin 10.1 grams (71 per cent), reticulocytes 0.8 per cent. The details of the hematologic response are shown in figure 1.

There was gradual clinical improvement. The soreness of the tongue and the diarrhea disappeared. When she was discharged after 166 days in the hospital she had gained 27½ pounds in weight and felt able to work.

*Case 2* E.R., a 54 year old Puerto Rican woman was admitted to the hospital in May 1948 complaining of progressive weakness, burning and soreness of the tongue and numbness of the extremities.

Family history and past history Irrelevant

Present illness Four years prior to this admission to the hospital her illness began insidiously with general debility and difficulty in walking. One and a half years later she developed soreness of the tongue and diarrhea consisting of liquid, foamy stools, light yellow in color. Following treatment with liver extract the diarrhea improved, the burning of her tongue disappeared and she gained in strength. She continued liver therapy for six months, then for economic reasons discontinued it. A few months later she again developed general debility and numbness of the legs, but no diarrhea. She was admitted to the hospital where a diagnosis of sprue was made. Following treatment with liver extract she improved clinically and hematologically and was discharged from the hospital forty-five days after admission. She failed to return for further treatment and one year later she was admitted to the hospital again, complaining of progressive weakness, soreness of the tongue and numbness of the lower extremities, but no diarrhea.

Physical examination showed a pale woman in no acute distress but obviously weak and chronically ill. The skin and mucous membranes were pale. The sclera had a slight icteric tint. The tongue was red at the tip and edges. The vibratory sense was intact.

Gastric analyses showed free hydrochloric acid in the gastric juice. Her initial blood values were: red blood cells 1.59 million, hemoglobin 5.0 grams (32 per cent), reticulocytes 0.1 per cent, as can be seen in figure 2. She was given a total of 205 micrograms of vitamin B<sub>12</sub> in nine injections in a period of 166 days. Twelve days after the last injection her blood values were: red blood cells 4.21 million, hemoglobin 9.7

FIG. 1.—Hemopoietic response of E. R. a patient with tropical sprue to vitamin B<sub>12</sub>.

FIG 3—Hemopoietic response of J. G. a patient with tropical sprue to vitamin B<sub>12</sub>

11.1 grams (72 per cent), reticulocytes 18 per cent. The details of her hematologic response can be seen in figure 2.

She had a striking clinical improvement and was discharged from the hospital 185 days after admission. Since then she has been seen several times and is doing her work and has remained well. Some numbness of both legs persists. The vibratory sense remained intact.

**Case 3 J G**—a 73 year old Puerto Rican woman was admitted to the hospital in June 1948 complaining of foamy diarrhea, burning of the tongue and general weakness.

**Family history**—One sister died probably of sprue or pernicious anemia. **Past history**—Irrelevant.

**Present illness**—She was well until six months prior to her admission when she lost her appetite, developed foamy diarrhea and soreness of the tongue. She rapidly lost strength and during the six months she was ill lost 68 pounds in weight.

**Physical examination** showed a very ill pale woman. She had atrophic glossitis. The abdomen was flatulent and distended.

**Gastric analysis** showed free hydrochloric acid in the gastric juice. Her initial blood values were: red blood cells 1.49 million, hemoglobin 5.5 grams (35 per cent), reticulocytes 0.2 per cent, as can be seen in figure 3. She was given a total of 200 micrograms of vitamin B<sub>12</sub> in eight injections in a period of 138 days. There was definite improvement in her stools. Twenty-four days after the last injection her blood values were: red blood cells 3.89 million, hemoglobin 11.6 grams (75 per cent), reticulocytes 1.2 per cent. The details of her hematologic response can be seen in figure 3.

#### COMMENT

The three patients with tropical sprue reported were repeatedly given injections of crystalline vitamin B<sub>12</sub> intramuscularly. Case 1 was given a total of 210 micrograms in nine injections ranging in amounts from 10 to 25 micrograms in a period of 147 days. Case 2 received a total of 205 micrograms in nine injections ranging in amounts from 10 to 25 micrograms in a period of 160 days. Case 3 was given a total of 200 micrograms in eight 25 microgram injections in a period of 138 days. In each case there was little or no detectable change for the first three or four days, then, when the reticulocytes began to rise in the peripheral blood on the fourth or fifth day, the patients began to feel better. Following the reticulocyte peak which occurred from the sixth to the ninth day the red blood cells and hemoglobin gradually increased. In each case there was gradual gain in strength, and in patients 1 and 2 who had diarrhea there was some improvement in their alimentary tract function although the stools did not become entirely normal.

No final conclusions as to dosage and intervals between injections can yet be made but no therapeutic agent thus far used in the treatment of tropical sprue has been so effective per unit of weight as vitamin B<sub>12</sub>.

#### SUMMARY

Three cases of tropical sprue were treated with repeated injections of vitamin B<sub>12</sub> and showed dramatic and sustained therapeutic responses.

# DICUMAROL THERAPY CONTROLLED BY THE STABILIZED THROMBIN METHOD FOR DETERMINATION OF PROTHROMBIN

By L. A. STERNBERGER, M.D.

**A**N ADEQUATE method of control for the anticoagulant effect of dicumarol is an essential condition for the evaluation of effectiveness and danger of this therapy. Such a method should control the action of dicumarol only, it should be independent of accidental variations in clotting factors due to other causes. As long as these requirements are not fulfilled, the optimal dosage of dicumarol cannot be determined with too large doses hemorrhage results, while too small doses make it impossible to obtain the full therapeutic effect of the drug.

Hitherto the one-stage method of Quick<sup>1</sup> or modifications of it have been used exclusively in clinical work. It rests upon the principle that if in the coagulation of blood plasma thromboplastin, calcium and fibrinogen concentration are kept constant the clotting time depends only on prothrombin provided that these four factors are the only coagulation factors existing. Thromboplastin is controlled by addition of excess of this factor. The activity of thromboplastin has to be determined by standardization with a relatively large number of normal control plasmas.<sup>2</sup> Since the normal controls are to be used for standardization of a reagent for the method, the absolute value of prothrombin in normals cannot be established. Calcium concentration is to remain at its constant optimum. But it was pointed out by Jacques and Dunlop<sup>3</sup> and by Quick<sup>4</sup> that the prothrombin time of hypoprothrombinemic oxalated plasma is very sensitive to changes in calcium concentration so that in such plasmas this requirement becomes very hard to fulfill. The prothrombin clotting time of hypoprothrombinemic undiluted plasma is compared with that of diluted normal plasma. Dilution with normal saline changes the fibrinogen concentration significantly and although Niesche and co-workers<sup>5</sup> have attempted to avoid this by using fibrinogen as diluent and Rosenfield and Tuft<sup>6</sup> by employing deprothrombinized plasma, the results have not been uniform.<sup>7</sup>

The one-stage method does not take into account any of the following coagulation factors, which are capable of influencing the prothrombin time: (1) Antithrombotic substances described by Astrup<sup>7</sup> and by Glazko and Ferguson<sup>8</sup> which destroy thrombin immediately after its formation. (2) Owren's fifth coagulation factor<sup>9</sup> which is required in addition to thromboplastin and calcium to convert prothrombin to thrombin, and variations of which may increase or decrease the prothrombin time. (3) Autocatalytic factors described by Astrup<sup>7</sup> and Owren.<sup>9</sup> Because of such factors the rate of conversion of prothrombin to thrombin is not constant. The principle of the one stage method is that the rate of conversion of prothrombin to thrombin is dependent on the concentration of prothrombin by a definite relationship. (4) Inhibition factors postulated by Ferguson and Glazko<sup>10</sup> and by Tocantins<sup>11</sup> which slow down the conversion rate of prothrombin to thrombin. Moreover, normal plasma may contain any number of unknown factors<sup>12</sup> which affect the thromboplastin used in the one stage method so that, as pointed out by Conley and Morse<sup>11</sup> results obtained with different thromboplastins are not comparable. In fact, serious doubts arise as to whether the one-stage method gives more than a rough estimate of plasma prothrombin. On the other hand, the evaluation of the effectiveness and safety of dicumarol therapy can be made only if a strictly reliable control method is available and practical, giving absolute results so that reports from one laboratory can be compared with those obtained in another.

The stabilized thrombin two-stage method<sup>12</sup> is independent of any of the above factors of inaccuracy and, in addition, gives results in absolute units. With the use

From the Department of Pathological Physiology, Hebrew University and the Pichard-Hadassah University Hospital, Jerusalem, Israel.

of the modification to be described in this paper (related particularly to the preparation of a stable thrombin reagent and to different quantities of materials used in the test) it does not take more time of performance than the one stage procedure. The method is based on our observation that alcohol suppresses the antithrombic activity of plasma, so that it becomes possible to keep constant the amount of thrombin obtained after quantitatively converting prothrombin to thrombin.

### METHOD FOR DETERMINATION OF PROTHROMBIN

#### *Principle*

The oxalated plasma used contains the prothrombin to be examined, as well as antithrombin and fibrinogen. First, the fibrinogen is removed by adding thrombin. Fibrinogen becomes thus converted to fibrin, and is rolled out with a stirring rod. The resulting fluid contains all the prothrombin, antithrombin, and the added thrombin (but not fibrinogen). However, within ten minutes the added thrombin will have been inactivated by the antithrombin present. Now the antithrombin activity will be suppressed by the addition of alcohol, and prothrombin converted to thrombin with human milk (thromboplastin) and calcium. The resulting fluid contains all the thrombin obtained quantitatively from the prothrombin originally present (but does not contain active antithrombin). It does not clot as such, because fibrinogen has been removed previously. The amount of prothrombin is now determined by adding various dilutions of the thrombin thus obtained to constant amounts of normal plasma and recording the thrombin-fibrinogen clotting times. This method is independent of the activity of the reagents used. Thus, prothrombin concentration can be directly read from the thrombin-fibrinogen clotting times, and no comparison with normal controls is necessary.

#### *Reagents*

- 25 per cent by volume of ethyl alcohol in normal saline solution
- 50 per cent by volume of ethyl alcohol in normal saline solution
- 0.1 M sodium oxalate solution
- 0.2 M calcium chloride solution
- Thrombin solution
- Fresh normal oxalate plasma
- Human milk

#### *Preparation of Thrombin Solution<sup>12</sup>*

A temperature between 16 and 22 C is maintained while the following ingredients are placed successively into a flask and stirred after each addition:

- 380 parts of 50 per cent by volume of ethyl alcohol in normal saline solution
- 145 parts of normal saline solution
- 25 parts of 0.2 M calcium chloride solution
- 210 parts of human blood (whole blood - 9 parts of blood obtained by venepuncture and rendered in coagulable by addition to 1 part of 0.1 M sodium oxalate solution)
- 75 parts of human milk
- 75 parts of 50 per cent by volume of ethyl alcohol in normal saline solution

The material obtained after the lapse of about 5 to 10 minutes (crude thrombin) will clot an equal volume of human plasma in 6 to 8 seconds. It is very stable. It may be processed immediately or may be kept in the refrigerator without loss of activity for at least eight months.

To 32 parts of crude thrombin (shaken well to obtain a uniform suspension) are added 18 parts of

95 per cent ethyl alcohol by volume. The whole is shaken violently and centrifuged immediately in an angle centrifuge. The sediment obtained is resuspended in 16 parts of oxalated merthiolate saline solution (prepared by placing 2 parts of 0.1 M sodium oxalate solution and 10 parts of 1 per cent merthiolate [sodium ethyl mercurithiosalicylate] into a volumetric flask and making up to 100 with normal saline solution). The suspension is stirred to break up the sediment as completely as possible, whereafter it is centrifuged and the sediment discarded. The supernatant thrombin solution will clot an equal volume of fresh oxalate plasma in 4 seconds. It is stable for at least six months storage in the ice box.

*Fresh human plasma.* Nine ml. of blood are drawn by venepuncture from a normal subject with as little trauma as possible and added immediately to 1 ml. of 0.1 M sodium oxalate solution contained in a centrifuge tube. The plasma is obtained by centrifugation.

*Human milk.* It may be used fresh or it may be stored in the ice box for at least one month. If milk has been stored it should be well shaken to obtain a uniform suspension.

#### *Procedure for the Determination of Prothrombin*

Four and five-tenths ml. of blood are drawn by venepuncture and added as rapidly as possible to a centrifuge tube containing 0.5 ml. of 0.1 M sodium oxalate solution. The tube is shaken immediately by inverting it three times. The plasma is obtained by centrifugation.

The procedure to follow is done at a temperature range between 16 and 22 degrees centigrade.

*Step one, defibrination.* 0.5 ml. of thrombin are added to 1.0 ml. of the plasma. After 10 minutes the liquid is expressed from the clot by wrapping the latter around a glass rod (using best a pipet with a broken, rough end).

*Step two, thrombinization.* To 0.75 ml. of defibrinated plasma there are added successively

1.75 ml. of 25 per cent by volume of ethyl alcohol in normal saline solution

1.25 ml. of 50 per cent by volume of ethyl alcohol in normal saline solution

0.3 ml. of human milk

0.075 ml. of 0.2 M calcium chloride solution,

shaking after each alcohol addition and after the addition of the calcium.

*Step three, dilution.* Serial dilutions of the thrombinized, stabilized plasma obtained in step two should be set up not earlier than 10 minutes after thrombinization, and preferably not later than  $1\frac{1}{2}$  hours thereafter. If stored, rather than fresh milk is used for thrombinization, dilutions should be set up only after the lapse of 20 minutes after thrombinization. For dilution, a 25 per cent (by volume) solution of ethyl alcohol in normal saline is used.

*Step four, clotting.* With a pipet graduated to the tip, 0.2 ml. of various dilutions of thrombinized plasma are drawn into Wassermann tubes containing 0.2 ml. of fresh human plasma. At the moment of contact with the plasma a stop-watch is started. The tube is held—after brief shaking—against a screened source of light (an electric bulb screened by placing filter paper in front of it proves satisfactory). The test tube is tilted in a way that the fluid contained in it is allowed to flow in turn along its walls from the bottom of the tube towards its top, and back to the bottom again, and the moment of appearance of granularity is recorded by stopping the stop-watch. (The fibrin appears in the form of granules, rather than of threads because of the presence of alcohol. Therefore, the tube should not be rotated but tilted. End points are very sharp, if this procedure is followed.)

*Evaluation of the Amount of Prothrombin by the Stabilized Thrombin Method*

Results with this method are obtained in absolute values, and no comparison with a normal standard is necessary. In order to obtain comparable results with the one-stage method, we fix the normal value of prothrombin arbitrarily as 100. This corresponds (see table 1) to a clotting time of 18 seconds obtained when adding to 0.2 ml. of normal plasma 0.2 ml. of a 1:10 dilution of thrombinized plasma (i.e., a 1:80 dilution of the original plasma). In hypoprothrombinemic plasma this value will be obtained at a correspondingly lower dilution.

We usually set up dilutions of 40, 20, and 10 per cent for samples presumably normoprothrombinemic, and dilutions of 80, 40, and 20 per cent for hypoprothrombinemic thrombinized plasmas. Occasionally also dilutions of 60 and 30 per cent are set up, particularly in cases in which the clotting time of 18 seconds seems to occur in between 80 and 40 per cent. If the values recorded as normal in table 1 do not coincide exactly with any one of the dilutions actually set up, but happen to lie in between them, the significance of this can be evaluated by comparing the

TABLE 1 *Clotting Times of Various Dilutions of Thrombinized Stabilized Plasma*

Dilution of thrombinized plasma	Corresponding dilution of original plasma	Clotting time
%	%	seconds
100	12.5	6.2
80	10.0	6.9
60	7.5	7.8
40	5.0	9.2
20	2.5	12.6
10	1.25	18.0
5	0.625	24.7

values obtained at the various dilutions tested and observing whether corresponding deviations of the clotting times occur at all these dilutions. With this procedure the following values of prothrombin can be determined with accuracy, (more definite recording would be within the limits of experimental error) 200, 150, 100, 75, 50, 35, 25, 20, 17, 14, 12.5, 11, 10, 8.5, 7, 6, 5.5 and 5. Standard error and standard deviation of the clotting times recorded in table 1 have been computed in a previous publication.<sup>12</sup>

## DICUMAROL TREATMENT

In this series, 43 cases were given dicumarol for a period of seven to forty-five days. These include 27 cases of pulmonary embolism, 7 cases of thrombophlebitis, 4 cases of arterial embolism, and 5 postoperative cases treated prophylactically. All cases of arterial embolism and the more severe cases of pulmonary embolism were also given heparin for the first one or two days of treatment, usually until the prothrombin reached a level of 50. Heparin was always given by continuous intravenous drop infusion, and the venous blood coagulation time kept between 15

and 21 minutes. It is noteworthy, that the determination of prothrombin with our method is not influenced by the amount of heparin in the blood, since it excludes the effect of antithrombin and is not dependent upon the conversion time of prothrombin to thrombin. Thus, unlike with the one-stage method,<sup>14</sup> continuous administration of heparin does not disturb the determination of prothrombin.

#### *The Prothrombin Level before Treatment*

Frequently patients showed a hyperprothrombinemia of 150 to 200 before treatment. This was particularly marked in patients with long standing thrombosis before institution of treatment, or in cases of pulmonary embolism, especially in recurrent pulmonary embolism. On the other hand, among 78 postoperative determinations of prothrombin, there were also 11 cases of hyperprothrombinemia, yet none of them did develop postoperative thrombosis or embolism. It is our impression that the presence of hyperprothrombinemia cannot be used to predict whether a patient is predisposed to thromboembolic disease. It seems, however, that some patients, if having already contracted a thrombosis, may, after a certain lapse of time, develop an occasional hyperprothrombinemia.

#### *Determination of Dosage*

In all our patients we endeavored to keep the level of prothrombin between 17 and 50. Dicumarol is a slow acting and very cumulative drug. In attempting to keep the patient at a certain maintenance level, it is necessary to determine the dose to be given on a certain day not only by the prothrombin level for that particular day, but also by the previous response of the patient. Such maintenance was accomplished by the following program of dosage:

First day Always 300 mg. are given

Second day In patients with thromboembolic disease, 200 mg. are given, in all prophylactic cases and in every weak or emaciated patient, 100 mg.

Third day If the prothrombin for that day is 100 or above, 200 mg. are given. If it is 75-100 mg. or less, no dicumarol is given.

Fourth and each subsequent day If the prothrombin is above 50, 200 mg. are given. If it is 50, and was on the preceding day above 50, 100 mg. are given. If it is 50 and was on the preceding day 50 or less, 200 mg. are given. If the prothrombin is 35, and was on the preceding day more than 35, no dicumarol is given. If it is 35 and was on the preceding day also 35, 100 mg. are given. If it is 35, and was on the preceding day less than 35, 200 mg. are given. If the prothrombin is less than 35, no dicumarol is given.

Using this program of administration of dicumarol in the stabilized thrombin method for the determination of prothrombin, it is easy to keep the prothrombin level between 17 and 50. During a total of 513 determinations of prothrombin in the hypoprothrombinemic maintenance period of dicumarol in this series, only in 12 determinations (2.3 per cent) was the prothrombin more than 50 and only in three instances (0.6 per cent) was it less than 17. Daily variations of prothrombin were smaller with this method of control than with the one stage method. This becomes obvious, if it is borne in mind that the one-stage method is dependent also

on other factors besides the quantity of prothrombin (as outlined above), while the stabilized thrombin method is a direct measure of the amount of prothrombin after it has been converted to thrombin

### Comparison with the One-Stage Method

In a number of cases we have been running parallel determinations with the one-stage method of Quick.<sup>1</sup> An example is given in figure 1. The dosage of dicumarol was determined by the results of the stabilized thrombin method. It will be seen that in the beginning of treatment prothrombin values fell off more rapidly and after stoppage of dicumarol returned more quickly to normal with the one-stage than with the stabilized thrombin method. This discrepancy is explained if consideration is

FIG. 1.—Course of Treatment in a Case of Bilateral Thrombophlebitis during Paratyphoid Fever (E. paratyphi B infection) Comparison of One Stage and Stabilized Thrombin Method

taken of the fact that the one-stage method is dependent on both, the quantity of prothrombin as well as the speed of conversion of prothrombin to thrombin, while the stabilized thrombin method is dependent only upon the quantity of prothrombin. It may well be that fresh circulating prothrombin is more active in its rapidity of conversion to thrombin than less recently formed prothrombin, while both, new and old prothrombin, still form the same amount of thrombin from a given amount of prothrombin. It was pointed out by Overman and co-workers<sup>18</sup> and by Witts<sup>19</sup> that dicumarol probably acts by inhibiting the formation of prothrombin in the liver through competition with vitamin K. Dicumarol hypoprothrombinemia is induced by slowing down the formation of new prothrombin. Therefore, in the beginning of the treatment, the relative amount of old prothrombin in circulation will predominate over that of newly formed prothrombin, and a lower value is obtained with the one-stage method than does correspond to the total amount of

prothrombin present. Upon stopping dicumarol new prothrombin is formed again, while the reserve of prothrombin in the circulating blood is relatively small. As a result the relative amount of newly formed prothrombin will predominate over that of old prothrombin, and a higher value of prothrombin is obtained with the one-stage method that does correspond to the quantity of prothrombin actually present. Similar results have been obtained by Hurn and Mann<sup>17</sup> in comparing the one-stage method with the two-stage method of Warner, Brinkhous, and Smith.<sup>18, 19</sup>

### *Treatment of Pulmonary Embolism*

Twenty-seven patients were treated. Thirteen of them had multiple emboli and were first seen only after a recurrent embolization. In none of these patients did dyspnea or cyanosis last for more than two days after the start of treatment, although 9 of the cases with recurrent pulmonary emboli were continually cyanotic and dyspneic from the time of occurrence of the first embolus till the second day after the start of treatment, i.e., for a period varying from 5 to 16 days (average 7 days). In only 1 of the 27 cases did a further infarction occur during treatment. It took place on the eighth day, and symptoms were mild. All patients recovered. They were allowed out of bed 3 to 7 days after all of the following conditions had been fulfilled: (1) absence of fever, (2) absence of blood in the sputum, (3) absence of large amounts of pleural exudate (but a patient was never kept in bed because of the presence of a few friction rales), (4) absence of continuous pain (few patients had still some slight pain on deep inspiration when first out of bed). Dicumarol therapy was continued for 1 to 2 days after the patient had been ambulatory. With this program the period of treatment in these 27 cases was minimum 5 days and maximum 30 days, average 16 days. The average daily dose of dicumarol was 121 mg. The time of recumbency of the patients had no relation to the initial severity of symptoms. The shortness of the period of morbidity is outstanding, particularly if it is considered that there was an exceptionally large proportion of severe cases in this series.

*Case Report.* A 54 year old man was admitted because of a repeated pulmonary embolus complicating thrombophlebitis. He was in a state of severe cyanosis and dulled consciousness. Respiration was of the Cheyne Stokes type; the pulse was too weak to be felt. Big rales could be heard from a distance. The patient had a generalized purpuric rash which was reported to have developed about three days before admission. The thrombocyte count was 180,000 per cu. mm.

The patient was given immediately 0.120 Gm. papaverine hydrochloride intravenously and was started upon a continuous intravenous drip infusion of heparin in glucose (100 mg. of heparin per 300 cc. of 5 per cent glucose solution). At the same time blood was withdrawn by venesection (300 ml.). Because of the severity of the condition the purpura was ignored and dicumarol was started. Heparin was discontinued after twenty-four hours of treatment.

The patient's condition improved rapidly. Twelve hours after the treatment had been started he began to respond to words; the cyanosis became less and the respiration regular. The pulse although still weak was improving.

After forty-eight hours the patient started to cough out a small amount of bloody, mammillary sputum; consciousness had fully returned; dyspnea had disappeared; cyanosis was fading. On the fourth day the patient wanted to get out of bed and on the fifth day there was no more blood in the sputum. On the eighth day the patient was allowed out of bed and on the ninth day treatment was ended.

In this case anticoagulant treatment was considered a matter of last resource and dicumarol was given, although the patient was having a purpuric rash on admission. Within twelve hours of treatment while heparin was being given the rosy purpuric spots became deep red in color. At this time the prothrombin was still 100. After interruption of heparin the purpura started to disappear while prothrombin was falling to be maintained at a level of 35. No erythrocytes were found in the urine at any time during the treatment.

### *Thrombophlebitis*

Seven cases, including 2 patients with thrombophlebitis during typhoid fever, were treated. In all but one patient did local pain disappear within three days of treatment. Some patients were seen first after having been suffering from the disease for weeks. In all patients there was a regression of the extent of local tenderness from the start of treatment on. In no case did pulmonary embolism develop. The period of treatment was minimum 4 days, maximum 45 days, average 19 days. The average daily dose of dicumarol was 119 mg.

### *Arterial Embolism*

There were only 4 cases of arterial embolism in this series. Three patients suffered from myocardial infarction and contracted emboli in the popliteal artery. They were given dicumarol and heparin (the latter was discontinued when the prothrombin level had reached 50) and in all of them the circulation had become restored within 4 days. All patients recovered from the myocardial infarction. One case of embolism of the retinal artery came to treatment only after vision had been lost for two days, and no improvement was observed during treatment.

### *Prophylactic Treatment*

Five cases were given dicumarol prophylactically after surgical intervention. Treatment was started on the second postoperative day and continued until the patient was out of bed. In none of these cases did thrombosis develop. The period of treatment was minimum 3 days, maximum 8 days, average 7 days. The average daily dose of dicumarol was 115 mg.

### *Relation of Dosage of Dicumarol to Clinical Condition*

The average daily dose of dicumarol was similar in all clinical conditions treated, although there were large individual variations. The most sensitive patient (pure prophylactic treatment) received a total of 400 mg during 8 days of treatment (average 50 mg daily), while the least sensitive patient (pulmonary embolism) received a total of 2400 mg during 12 days of treatment (average 200 mg daily).

### *Complications*

The only complication of dicumarol treatment is hemorrhage due to excessive hypoprothrombinemia. In this series there was only one case of bleeding (2 per cent). This was a wound hemorrhage in a cachectic patient receiving prophylactic treatment. As we desired, in this series, to establish the usefulness of our method of control we have never hesitated to give dicumarol to patients with relative contraindications to the use of anticoagulant therapy (see the case of purpura described

above) We believe that the hemorrhage did occur only because of disregard of such contraindications

*Case Report* A two-stage Lahey's abdominoperineal resection of a reticulosarcoma of the rectum was performed by Dr. Joseph on a 60 year old emaciated man. After the second operation he was rather dehydrated and was lying in bed listlessly without making any spontaneous movement. Prophylactic dicumarol treatment was instituted on the fourth postoperative day and continued until the eleventh postoperative day, as shown in the following table

Date	Prothrombin	Dicumarol (Gm.)
August 11	100	0.3
August 12		0.1
August 13	50	—
August 14	35	—
August 15	25	—
August 16	25	—
August 17	17	—
August 18	1 a.m. 12.5 9 a.m. 17	

The patient was very sensitive to small doses of dicumarol. The blood-tinged discharge from the perineal wound was present before and during the whole course of treatment, but the amount of blood did not increase until August 17. On this day prothrombin was still falling. Because of the anemia and general weakness the patient was given a transfusion of 800 ml. of banked blood. Fresh blood was not used because this transfusion was not given for hypoprothrombinemia. At 1 a.m. the following morning (August 18) 8 hours after this transfusion blood started to ooze from the operative wound. At this time prothrombin was 12.5. Immediately thrombin<sup>12</sup> was injected into the wound cavity and cessation of bleeding was instantaneous. The patient was also given Hykinone (menadiol bisulfite, Abbott) 0.072 Gm. by slow intravenous injection. Eight hours thereafter the prothrombin was 17 and bleeding did not recur. The patient made an uneventful recovery.

It may be possible that administration of banked blood diluted the patient's circulating prothrombin and thus initiated the bleeding. Also any of the following contraindications to the use of dicumarol may have predisposed to the bleeding: (1) an extensive, infected, operative wound,<sup>20</sup> (2) surgery of the gastro-intestinal tract,<sup>20</sup> (3) dehydration and cachexia.<sup>21</sup>

In all our patients repeated urinalyses for a search of erythrocytes were made. In none did microscopic hematuria appear during treatment, while in those patients who were treated after surgery of the urinary tract, hematuria never became more marked and often disappeared during dicumarol administration.

With the stabilized thrombin method it is possible to keep the patient well within the boundaries of the therapeutic zone and variations of prothrombin from day to day are relatively small. There were only three hyper-reactors (7 per cent) in this series, out of which only one (2 per cent) had a hemorrhage, and this would have been prevented, had we excluded cases with contraindications to dicumarol. With the use of the one-stage method 16.6 to 27 per cent of hyper-reactors are encountered,<sup>\*</sup> and hemorrhagic complications occur in 4.7 to 20 per cent, average 8.3 per cent.<sup>22</sup>

## CONCLUSIONS

The stabilized thrombin method for the determination of prothrombin is the only procedure which determines prothrombin quantitatively and is independent of other coagulation factors. Since it is independent of the activity of the reagents used, no normal controls are necessary.

In using the stabilized thrombin method for control of the clinical administration of dicumarol rather constant hypoprothrombinemic levels could be attained, and daily variations of prothrombin were relatively small. There were less hyperreactors and less hemorrhages than would be expected with the use of the one-stage method. Rarely did a patient's prothrombin rise above the therapeutic range during treatment.

The ease with which such safe and effective therapeutic levels can be maintained is explained by the fact that, while the one-stage method is dependent upon a number of coagulation factors, the stabilized thrombin method is a direct quantitative estimation of only prothrombin.

## ACKNOWLEDGMENTS

I am greatly indebted to Professor E. Wertheimer, Chief of the Department of Pathological Physiology, Hebrew University and Director of the Chemical Laboratory, Rothschild Hadassah University Hospital. His suggestions and encouragement have been an invaluable aid during this work.

The cooperation of Dr. Rachmilewitz, Dr. Kleeberg, Professor B. Zondek, Dr. Joseph and Dr. Nissel is also gratefully acknowledged.

# THE EFFECT OF FOLIC ACID ON THE TOXICITY OF ITS ANALOGUE 4-AMINOPTEROYLGLUTAMIC ACID (AMINOPTERIN)

By GEORGE M. HIGGINS, PH D

*With the technical assistance of MURIEL STEMBER AND HARRY MONSEN*

EVER since Woods<sup>1</sup> described a competition between sulfanilamide and para aminobenzoic acid for an enzyme system related to the use of this vitamin in metabolic processes, widespread interest has centered on the synthesis of analogues which are chemically related to a metabolite but which seriously interfere with its normal function. There are now available a large number of these metabolite antagonists<sup>2</sup> which in very minute amounts seriously interfere with the functions of cell catalysts, such as vitamins and hormones.

Such antagonists or displacing agents have now been synthesized for every known member of the vitamin B-complex. Martin, Tolman and Moss<sup>3</sup> prepared the first antagonist to pteroylglutamic acid. They produced methylfolic acid, which was shown to be an effective displacer of folic acid with a ratio of inhibitor to metabolite of 1:150. The growth-promoting action of pteroylglutamic acid for *Streptococcus faecalis* R was antagonized by this analogue.

Franklin, Stokstad, Belt and Jukes<sup>4</sup> fed a crude antagonist, prepared by Hultquist and Smith, to weanling rats. This preparation accelerated and intensified the signs of pteroylglutamic acid deficiency in their rats, lowering hemoglobin levels and granulocyte counts and seriously impairing the maturation of cells in the bone marrow. These effects were all completely prevented, however, by the addition of suitable amounts of pteroylglutamic acid to the diet. Similar results were obtained by giving this same antagonist to mice and to chicks.<sup>5</sup> Pteroylglutamic acid in appropriate amounts also prevented the appearance of this syndrome in these animals. Welch and colleagues<sup>6</sup> provided the same crude antagonist to a pig which was fed a purified diet. They noted a retarded growth rate, alopecia, anorexia, profuse diarrhea and severe anemia. The interference with normal metabolism by the antagonist was removed by giving a crude source of extrinsic factor, essentially free of pteroylglutamic acid, together with normal human gastric juice.

More recently, another analogue of the vitamin, 4-aminopteroylglutamic acid, known as aminopterin, has been synthesized<sup>7</sup> and experimentally tested on mice.<sup>8</sup> This analogue was produced by the replacement of the hydroxy group of the pteridine ring by an amino group, resulting in a much more potent analogue than the 7-methylfolic acid produced by Martin and colleagues.

Since conjugates of folic acid—namely pteroyltriglutamic acid and pteroyldiglutamic acid—have been shown to produce an acceleration of the leukemic process in children, it was concluded that the use of antagonists of pteroylglutamic acid in such cases was certainly indicated. Accordingly, Farber and col-

leagues<sup>9</sup> reported their early results of the use of the more recently synthesized antagonist, 4-aminopteroylglutamic acid, in the treatment of a series of 16 children who had acute leukemia. Marked clinical improvements were noted, and influences were exerted on the immature cells of the peripheral blood, the spleen and lymph nodes. However, the toxic effects which accompanied the use of analogue were severe, including stomatitis and early ulceration.

Stickney, Hagedorn, Mills and Cooper<sup>10</sup> reported that administration of this analogue produced remissions in the clinical course of certain patients who had acute leukemia. In some cases, however, improvement was not elicited. Toxic symptoms, including stomatitis, diarrhea, alopecia and deafness, were recorded. Jacobson, Levin and Holt<sup>11</sup> studied 10 patients with acute leukemia who received aminopterin or methopterin (10-methylpteroylglutamic acid). They concluded that methopterin was superior to aminopterin in the treatment of such leukemias in view of the fact that it was less toxic.

Pierce and Alt<sup>12</sup> reported their results with aminopterin in a series of cases of acute leukemia. Remissions characterized by a severe marrow aplasia followed by rapid regeneration were obtained in 5 of the 11 cases. Berman, Axelrod, Vonder-Heide and Sharp<sup>13</sup> reported their results with the use of aminopterin in 9 patients with chronic leukemia. Although they recognized definite hematologic effects, subjective improvement in any patient was not claimed. They, too, described the toxic effects which followed the administration of the drug.

Since all reports to date indicate that the severe toxic reactions which ensue on administration of this analogue must restrict any extended clinical use of it in spite of its therapeutic value, we undertook a study, in white rats, of some of the toxic manifestations of the analogue together with the modifications of those reactions which were induced when folic acid was given together with aminopterin.

## METHODS

Fifty six young healthy male white rats weighing from 110 to 130 Gm. were selected from our Institute colony. These were arranged into seven groups of 8 animals each so that the average weight of rats composing each group was essentially alike. All animals were maintained in metal cages on open meshwork screens thus greatly restricting coprophagy. Our standard laboratory ration was provided ad libitum and water was available at all times in water bottles attached to the cages.

Six of the seven groups served as test groups and one as an uninjected control. Aminopterin was given intraperitoneally in amounts equivalent to 50 micrograms daily and folic acid was given by stomach tube daily. The various test groups were arranged as follows: each animal in group A received aminopterin alone. Each animal in group B received the same amount of aminopterin plus 5 mg. of folic acid. Group C received aminopterin plus 10 mg. of folic acid. Group D received aminopterin plus 20 mg. of folic acid. Group E received aminopterin plus 30 mg. of folic acid. Group F received aminopterin plus 50 mg. of folic acid. The animals of Group G were given neither aminopterin nor folic acid and served as a normal control group.

At the end of the sixth day the heart blood of all surviving animals was sampled and the white blood and leukocyte tabulations and the differential distributions were recorded. Each animal was kept by etherization and the spleen, adrenals and thymus were removed and weighed on a precision balance.

<sup>4</sup> 4-aminopteroylglutamic acid was made available for our use by the Lederle Laboratories, New York, to whom we are extremely grateful.

Bone marrow imprints were made of samples of marrow obtained from the distal third of the femur. These imprints were stained by the May-Grünwald-Giemsa technic.

## RESULTS

1 *Body Weight Changes* The changes in the weights of these test animals given aminopterin and the influences exerted by varying daily amounts of folic acid are shown in figure 1. For the first three days, increases of weight were recorded for all animals, but those receiving the analogue without the vitamin gained only 2 Gm. during that three-day period. Greatest gains were recorded by the animals receiving the analogue plus 5 mg. of folic acid, although all vitamin-supplemented rats gained more than the controls, which were fed the standard ration.

FIG. 1.—Changes in body weights of animals receiving aminopterin and those receiving aminopterin plus varying amounts of folic acid.

and given neither analogue nor vitamin. The data indicate, for the first three days, that the analogue was not seriously toxic and that even the smallest amounts of the vitamin counteracted its effects.

After the third day, however, the toxicity of the analogue was clearly indicated. A severe loss of weight occurred on the fourth day in all animals receiving the analogue alone (group A), and 5 mg. of folic acid was ineffective in preventing loss of weight. Gains of weight, however, were recorded for all animals receiving the larger amounts of vitamin. Ten milligrams of folic acid daily failed to inhibit the toxic effects of the analogue after the fourth day, and 20 mg. of the vitamin did not prevent the loss of weight induced after the fifth day. Thirty milligrams and 50 mg. of the vitamin when given with the analogue maintained

body weights during the fifth and six days, but increases of weight were not recorded

2 *Gross Appearance* The marked contrast in the appearance of animals receiving aminopterin alone and those receiving the analogue plus the vitamin is clearly portrayed in figure 2a and b. The rough coat, the stained hair, the encrusted eyelids and ears, and the extreme diarrhea were all prevented, during the six-day test period, by the administration of 30 mg of folic acid daily by mouth together with the daily intraperitoneal administration of aminopterin.

FIG. 2a—Animal receiving aminopterin without folic acid. b Animal receiving aminopterin plus 30 mg of folic acid daily for six days.

3 *Food Intake* Extreme anorexia was not evident until the third day of the test period, but the average intake of all animals taking the analogue without the vitamin was less than 1 Gm a day (fig 3). The addition of 5 mg of the vitamin stimulated the appetite only slightly, although 10 mg daily increased the food intake to more than three times that of animals taking the analogue alone and 30 mg of folic acid, when given with the analogue, so stimulated the appetite as to maintain an average food intake in excess of 9.0 Gm daily. However in the amounts given, folic acid did not so nullify the effects of its analogue as to maintain appetites in any test animal equal to those of animals constituting the untreated control group.

4 *The Weight of the Adrenal Glands* The adrenal glands invariably reflect onto-

ward reactions of an organism to toxic substances. Hyperplasia of the adrenal cortex, together with marked atrophy of the thymus, constitutes part of a syndrome embracing the reactions of an organism to unfavorable environments induced by a number of different factors. In this test, too, of the toxicity of aminopterin, the increased weights of the adrenal glands indicated an untoward reaction of the animals toward the drug.

The combined weights of the adrenal glands recorded at necropsy of all surviving animals of all seven groups on the sixth day are graphically portrayed (fig. 4). The average combined adrenal gland weight of all control animals was 20.0 mg, but in the group given aminopterin alone (A) the average combined

FIG. 3—The degree of anorexia induced in animals by giving aminopterin and by giving aminopterin plus varying amounts of folic acid.

weight of the adrenals was slightly in excess of 51.0 mg. The addition of only 5.0 mg. of folic acid daily reduced the average combined weight of the adrenal glands to 41.5 mg., and the administration of 30 mg. of folic acid daily to animals given the analogue resulted in restricting the weight of both adrenal glands to 28.0 mg. The administration of 50 mg. of the vitamin daily was less effective than that of 30 mg. in restricting hyperplasia.

5. *The Weight of the Thymus* Atrophy of the thymus constitutes a part of the syndrome which ensues within an animal on the administration of toxic or harmful substances, so that atrophy of the thymus usually accompanies adrenal hypertrophy. The data obtained by weighing the thymus of all animals at necropsy are

FIG 4—Weights of the adrenal glands of animals receiving aminopterin and those receiving aminopterin plus varying amounts of folic acid, when the animals were killed on the sixth day

FIG 5—Weights of the thymus of animals receiving aminopterin and those receiving aminopterin plus varying amounts of folic acid when the animals were killed on the sixth day

recorded in figure 5, and photographs of the glands of 2 animals receiving aminopterin and of 2 animals receiving aminopterin plus 30 mg of folic acid daily are shown (fig 6)

The average weight of the thymus of the 8 control animals (group G) was slightly less than 400 mg, while that of animals receiving aminopterin alone (group A) was slightly less than 150 mg. The range of thymus weight of animals within group A extended from 59.6 mg to 296.8 mg. The administration of the various amounts of the vitamin (pteroylglutamic acid) had a considerable influence on restricting the extent of the atrophy, but the daily administration of 50 mg of the vitamin resulted in maintaining an average thymus weight of 320.5 mg, a figure considerably less than that recorded for the control animals (group G).

6 *The Weight of the Spleen* The size of the spleen is ordinarily not a reliable criterion for recording systemic reactions. A vascular organ, with capillaries and venous sinuses, the spleen is subject to rather rapid changes in size, correlated with the extent to which fluid or other blood constituents are sequestered within it. Splenic size varies considerably with the anesthetic agent used. Ether has a constricting effect on the organ, while pentobarbital sodium (nembutal) will ordinarily dilate the sinuses and enlarge it.

FIG. 6—Thymus of animals receiving aminopterin without folic acid (left) and of animals receiving aminopterin plus 30 mg of folic acid daily (right)

Since the data herein reported were obtained on animals correspondingly etherized, there is reason to believe that they constitute a reasonably accurate response of the spleen to the experimental restrictions imposed by the study. The data assembled on the weights of the spleens of all animals are given in figure 7.

Since aminopterin inhibits blood cell formation, it is obvious that the spleen, a blood-forming organ, would be affected by this drug. Our data indicate wide variability in the size of the spleen in animals receiving aminopterin alone (group A). In some instances the spleen appeared as a narrow pale band of tissue, weighing as little as 91.8 mg, in others it was more nearly normal, and in one animal it weighed 408.4 mg. The average weight of the spleen encountered for group A was 266.0 mg, which is considerably less than the average weight recorded for the control group G, namely, 600.0 mg. Photographs of the spleens of 2 animals receiving the drug and of those of 2 animals receiving the drug plus the vitamin are shown (fig. 8).

As in the data assembled on adrenals and thymus, so in those recorded for the weights of the spleens of the various groups, folic acid in the amounts given

FIG 7—Weights of the spleens of animals receiving aminopterin and those receiving aminopterin plus varying amounts of folic acid when the animals were killed on the sixth day

FIG 8—Spleens of animals receiving aminopterin without folic acid (left) and of animals receiving aminopterin plus 30 mg of folic acid daily (right)

The average weight of the thymus of the 8 control animals (group G) was slightly less than 400 mg, while that of animals receiving aminopterin alone (group A) was slightly less than 150 mg. The range of thymus weight of animals within group A extended from 59.6 mg to 296.8 mg. The administration of the various amounts of the vitamin (pteroylglutamic acid) had a considerable influence on restricting the extent of the atrophy, but the daily administration of 50 mg of the vitamin resulted in maintaining an average thymus weight of 320.5 mg, a figure considerably less than that recorded for the control animals (group G).

6 *The Weight of the Spleen* The size of the spleen is ordinarily not a reliable criterion for recording systemic reactions. A vascular organ, with capillaries and venous sinuses, the spleen is subject to rather rapid changes in size, correlated with the extent to which fluid or other blood constituents are sequestered within it. Splenic size varies considerably with the anesthetic agent used. Ether has a constricting effect on the organ, while pentobarbital sodium (nembutal) will ordinarily dilate the sinuses and enlarge it.

FIG. 6—Thymus of animals receiving aminopterin without folic acid (left) and of animals receiving aminopterin plus 30 mg of folic acid daily (right)

Since the data herein reported were obtained on animals correspondingly etherized, there is reason to believe that they constitute a reasonably accurate response of the spleen to the experimental restrictions imposed by the study. The data assembled on the weights of the spleens of all animals are given in figure 7.

Since aminopterin inhibits blood cell formation, it is obvious that the spleen, a blood-forming organ, would be affected by this drug. Our data indicate wide variability in the size of the spleen in animals receiving aminopterin alone (group A). In some instances the spleen appeared as a narrow pale band of tissue, weighing as little as 91.8 mg, in others it was more nearly normal, and in one animal it weighed 408.4 mg. The average weight of the spleen encountered for group A was 266.0 mg, which is considerably less than the average weight recorded for the control group G, namely, 600.0 mg. Photographs of the spleens of 2 animals receiving the drug and of those of 2 animals receiving the drug plus the vitamin are shown (fig. 8).

As in the data assembled on adrenals and thymus, so in those recorded for the weights of the spleens of the various groups, folic acid in the amounts given

FIG 7—Weights of the spleens of animals receiving aminopterin and those receiving aminopterin plus varying amounts of folic acid, when the animals were killed on the sixth day

FIG 8—Spleens of animals receiving aminopterin without folic acid (left) and of animals receiving aminopterin plus 30 mg of folic acid daily (right)

maintained more nearly normal weights than in group A. Five milligrams of the vitamin exerted a considerable effect, but 30 mg daily maintained in group E an average spleen weight (525.0 mg) closely approaching the average weight in the untreated controls.

7 *The Changes in Leukocytes in the Peripheral Blood* Aminopterin markedly restricted the total number of leukocytes in the peripheral blood of these young rats. In a series of 8 rats, selected from the same age group as those used to test the effects of this analogue, and known as a preinjection control group, the total leukocyte count was 14,000 cells per cubic millimeter of blood. Of these, approxi-

FIG. 9.—Distribution of leukocytes in the peripheral blood of normal animals, those receiving aminopterin, and those receiving aminopterin plus varying amounts of folic acid daily, on the sixth day of the experiment.

mately 11,000 were lymphocytes and 3,000 were neutrophilic leukocytes, but small percentages of eosinophilic and basophilic leukocytes and monocytes were present. The data herein reported are restricted to a consideration of the reduction in the absolute numbers of lymphocytes and neutrophilic leukocytes per cubic millimeter of blood imposed by aminopterin and of the influences exerted by giving the varying amounts of folic acid to such aminopterin-treated animals (fig. 9).

Six days of the intraperitoneal injection of the analogue, in the amounts selected, reduced the total numbers of lymphocytes and neutrophilic leukocytes to 3,800 per cubic millimeter of blood. Accepting the data of the preinjection control group as standard, or representative of the blood of the test groups before injec-

tions began, it is obvious that aminopterin restricted both categories of white blood cells. The total number of lymphocytes dropped from a level of 11,000 to one of 3,300 per cubic millimeter, and the total number of neutrophilic leuko-

FIG. 10.—Imprints of the femoral bone marrow. *a* Normal rat. *b* Animal receiving aminopterin daily for six days. *c* Animal receiving aminopterin daily for six days plus 5 mg. of folic acid daily. *d* Animal receiving aminopterin daily for six days plus 30 mg. of folic acid daily. *e* Animal receiving aminopterin daily for six days plus 50 mg. of folic acid daily.

cytes dropped from a level of 3,000 to one of 500 cells per cubic millimeter. The smallest amount of the vitamin administered (5 mg. daily) had no effect whatever on the total number of neutrophilic leukocytes but did considerably elevate

the total lymphocyte count. For reasons difficult to interpret, 10 mg of the vitamin daily resulted in a considerable increase in the total numbers of neutrophilic leukocytes—up to 2,200 cells per cubic millimeter—and 5,800 lymphocytes for the same amount of blood, while those animals receiving the larger amounts of the vitamin—20, 30, and 50 mg respectively—had lesser numbers of neutrophilic cells. Increased numbers of lymphocytes, however, were found to occur in animals receiving 50 milligrams of the vitamin daily (group F), nearly approximating the lymphocyte level which obtained in the postinjection control group (G).

8 *The Bone Marrow* Imprints of bone marrow from the distal end of the femur were obtained at necropsy from representative animals of each group. These were stained by the May-Grunwald-Giemsa technic. Figure 10 rather well portrays the changes which ensued when the analogue was given and the modifications of these changes which followed the administration of the varying amounts of the vitamin together with the analogue.

Normal rat marrow contains cells of both the erythroid and the myeloid series in varying stages of maturation (fig. 10a). Attempts were not made in the present study to establish changes in the percentage distributions of the various cellular categories, but it was clearly obvious that marked inhibitory changes were in cited. A glance at the marrow preparations of animals receiving the analogue for the six days (fig. 10b) shows how completely the maturation of the myeloid cells had been suspended. These imprints show that the marrow, in the region examined, was composed of cells almost exclusively erythroid, although a very few early myeloid forms were present.

The administration of 5 mg of folic acid to animals receiving the analogue in cited a slight myeloid response (fig. 10c), although the smears indicated that the marrow was still largely erythroid. But there were larger numbers of myelocytes and metamyelocytes in the imprints stimulated by the added small amount of vitamin. The response of the bone marrow to the increasing amounts of folic acid was more nearly proportional to the amounts injected than in any other organ observed. As the amounts of the vitamin were increased, the percentages of myeloid cells in the marrow were correspondingly elevated. When 30 mg of the vitamin were given, larger numbers of immature myeloid cells were identified in the imprints, and their maturation resulted in many fully mature granulocytes (fig. 10d). The oral administration of 50 mg of the vitamin resulted in the retention of a marrow pattern which was entirely normal (fig. 10e). The numbers of mature granulocytes appeared even to exceed those accepted as a normal distribution.

#### COMMENT

This study, incomplete though it is with respect to all the many other toxic reactions induced by the analogue, was undertaken to determine the extent to which the vitamin, folic acid, would counteract the untoward effects of the antagonist, 4-aminofolic acid. The therapeutic effects of this folic acid antagonist are of sufficient value clinically to warrant studies directed toward a modification of the toxic symptoms which accompany its use. If the analogue could be so modified as to

restrict the extreme degrees of enteritis which develop on its administration and yet retain the marked inhibitory effect on the development of myeloid cells in the bone marrow, its effective clinical use would be assured.

By the administration of the vitamin together with the analogue we have demonstrated satisfactorily that, for a certain period, a given amount of vitamin will completely nullify a given amount of antagonist. The toxic reactions which were so severe in animals of group A, given aminopterin alone, included anorexia, atony of the entire gastro-intestinal tract with gastric and intestinal distention, marked diarrhea, adrenal hyperplasia and atrophy of the thymus, spleen and bone marrow, with resulting leukopenia.

Partial remission of these disorders was obtained by giving small amounts of the vitamin daily, but larger amounts, 30 mg. daily, essentially inhibited the destructive effectiveness of the analogue in all of the categories enumerated. To be sure, a complete return to normal gland weights and to normal blood levels was not attained in all animals receiving that amount of folic acid daily, yet the gross appearance of the animals, the character of the gastro-intestinal tract, and the restored appetite all certified to the general deduction that, for the six-day test period, it required 30,000 micrograms of folic acid daily to counteract the toxic effects of 50 micrograms of 4-aminofolic acid daily. This is a ratio of inhibitor to metabolite of 1:600.

The toxic effects of aminopterin are not immediately evident on its administration. For three days, animals showed no ill effects of its intraperitoneal administration. Then, extremely rapidly, even over night, all the foregoing toxic manifestations may present themselves. This delay in the onset of symptoms, we presume, is due to the presence of a reserve of folic acid in the organism at the outset of the experiment. It may be that as soon as the analogue had destroyed this reserve of the vitamin, the toxic symptoms appeared. And yet these symptoms cannot all be ascribed to a folic acid deficiency, for we are not aware that they ensue to this extent in animals fed diets deficient in folic acid. Nevertheless, they did not develop when large amounts of the vitamin were fed, for the six-day period, together with aminopterin.

Although this report covers a short-time study of the relationship of the vitamin, folic acid, to the toxicity exerted in rats by the antagonist, aminopterin, and shows unquestionably the inhibition exerted by the vitamin for a six-day period, yet we have other data which show that this inhibition was not effective indefinitely. Our results show that the characteristic syndrome incited by the amounts of aminopterin we administered, was not inhibited for periods longer than fourteen days by giving 30 mg. of folic acid daily. We have not extended our observations to include the results of giving 50 mg. of the vitamin for the longer period. Reasons for the failure of the vitamin to inhibit the antagonist for longer periods are not clear. It may be that further increase of the amounts of folic acid could well antagonize the analogue, so as to restrict permanently the onset of the toxic effects. There is need, therefore, for much more research on the functional interrelationships of this vitamin and its powerful antagonist, aminopterin.

## SUMMARY AND CONCLUSIONS

A study of some of the toxic reactions of 4-aminofolic acid together with the modifications of these reactions induced by giving varying amounts of folic acid daily to white rats is reported

Seven groups of young male rats ranging in weight from 110 to 130 Gm were arranged. Aminopterin (4-aminofolic acid) was given intraperitoneally, in amounts equivalent to 50 micrograms daily, to all rats of six of these seven groups. Folic acid was given by mouth to these animals in such amounts as to provide 5, 10, 20, 30 or 50 mg daily to each animal respectively of five of the six groups receiving aminopterin. One group received the analogue without the vitamin. One group of 8 animals received neither the vitamin nor its analogue.

Observations continued for six days, when all surviving animals were killed and necropsy was performed. Data were assembled on the appetite, body weights, the weights of adrenals, thymus and spleen, the distribution of leukocytes in the peripheral blood and the changes in the bone marrow. The following conclusions seem warranted:

1. Aminopterin is extremely toxic and incites within six days anorexia, extreme diarrhea with atony of the entire gastro-intestinal tract, adrenal hyperplasia, atrophy of the thymus and spleen, and an inhibition to development of myeloid cells in the bone marrow.

2. Small amounts of folic acid are essentially without effect on the toxicity of that amount of the analogue we chose to administer.

3. Larger amounts of folic acid daily (30 mg) proved effective in essentially inhibiting the development of the severe toxic reactions for the six-day period.

4. The severe toxicity of aminopterin does not manifest itself until the third or fourth day of its daily administration. The onset of these symptoms is thereafter extremely rapid.

5. Thirty milligrams of folic acid daily will not indefinitely counteract the toxic symptoms induced by 50 micrograms of aminopterin. In our experience, within twelve to fourteen days, the characteristic syndrome will appear in spite of the continuous administration of the vitamin.

# ERYTHROCYTOPOIESIS IN THE NERVOUS SYSTEM OF THE EMBRYONIC RAT

By MATTHEW BLOCK, M D , Ph D

IN THE course of experiments to influence embryonic hematopoiesis in rats<sup>1</sup> the constant occurrence of erythrocytopoiesis in various parts of the embryonic central and peripheral nervous system was observed. The following is a description of erythrocytopoiesis occurring in this site and indicating its origin and relation to erythrocytopoiesis in other sites of the rat embryo and a discussion of the implications of the existence of this previously undescribed site of erythroblastic activity. The histologic description applies to both normal embryos and to those subjected to various stimuli to modify hematopoiesis since the microscopic appearance of the tissues in these two groups was identical in all embryos of corresponding age.

## MATERIAL AND METHODS

The ages of the embryos and the stimuli used to modify hematopoiesis have been described in detail in a previous investigation.<sup>1</sup> In brief, there were 25 rat embryos in the experimental series varying from 8 to 18 days of development with most of the embryos being 14 to seventeen days of development. The pregnant rats were subjected to the following stimuli in the experimental series, injections of saprotoxin, phenylhydrazine, dinitrophenol, concentrated liver extract and Evans blue, feedings of thyroid extract, exposure to chloroform vapor, and repeated withdrawal of blood by cardiac puncture.

At least one normal embryo was studied for each day of intrauterine development until birth on the twenty-first day of gestation. During the fourteen to seventeen day period at least two normal embryos were studied for each day of development. In addition, in the laboratory of Professor William Taliaferro of the Parasitology Department, rats known to be Bartonella-free were mated and 16 and 17 day embryos were obtained for study.

The embryos were fixed for two to six hours in Zenker-formol, embedded in nitro-cellulose and cut serially at 8 micra. The slides were stained with hematoxylin eosin-azure II and Mallory-azan. Some slides were impregnated by means of the Bielschowsky technic for reticular fibers and counterstained with Mallory azan.

## MICROSCOPIC OBSERVATIONS

*Eleventh Day* The central nervous system consists of a tube whose walls are made up of undifferentiated neuro-epithelium, and which is separated from the

From the Department of Medicine University of Chicago Chicago Ill

This work was aided by a grant from the Dr. Wallace C. and Clara A. Abbot Memorial Fund of the University of Chicago. Supported in part by a grant from the American Cancer Society on recommendation of the Committee on Growth of the National Research Council.

surrounding mesenchyme by an external limiting membrane. The cerebrospinal and sympathetic ganglia are also made up of an undifferentiated neuro-epithelium. Vascularization of the central and peripheral nervous system has not yet begun.

The cells of the neuro-epithelium and of the mesenchyme resemble each other quite closely but may be distinguished with some difficulty. The former have a smooth homogeneously stained cell body which has a rectangular or oblong shape, the latter have a finely vacuolated cell body that is irregularly stellate in shape. The chromatin particles in the nuclei of the neuro-epithelial cells are heavier and fewer in number than in the mesenchymal cells.

*Twelfth Day.* Neuroblasts, are now recognizable because of the presence of the characteristic oval nuclei with smooth fine nuclear membranes and round nucleoli. In addition, in favorably oriented sections naked axones may be traced from the cell bodies of these cells into the mesenchyme. The supporting cells (spongioblasts) of the nervous system at this stage have not differentiated into the various types of glia. In contrast to the mesenchymal cells, the neuro-epithelial cells are arranged in epithelial sheets, even in the ganglia. The neuro-epithelial cells may still be discriminated from the mesenchymal cells by the previously described criteria except at the edge of the ganglia and along the origin of the nerve roots where the neuro-epithelial cells lose their sheetlike arrangement and the individual cells become somewhat stellate.

By the twelfth day capillaries have begun to grow into the central nervous system and peripheral ganglia. Numerous mitoses are present in the endothelial cells. At this point the external limiting membrane of the central nervous system seems to be pushed in by the capillary endothelium and reflected over the outer surface of the endothelium. In the central nervous system, the endothelial cells rest directly against the surrounding neuro-epithelium. At this time there are no perivascular spaces and no perivascular mesenchymal cells (fig. 1a and b). There is no external limiting membrane in the ganglia and the vessels seem to penetrate directly in between the neuro-epithelial cells.

The endothelial cells (fig. 1a) at this stage of development may be separated from the supporting neuro-epithelial cells (fig. 1b) by the following criteria. The nucleus of the endothelial cell (fig. 1a) has finer, sharper chromatin particles and a more irregular and larger nucleolus than the neuro-epithelial cells (fig. 1b). The nuclear sap is paler in the endothelial cell nucleus and the nuclear membrane is finer and sharper. The endothelial cell cytoplasm extends parallel to the long axis of the vessel in contrast to the irregularly stellate, poorly demarcated spongioblast cytoplasm. However, it must be emphasized that these differences, although constantly present, are minute, especially in the ganglia. During the remainder of embryonic life the neuro-epithelial cells, except for the Schwann cells and the satellite cells supporting the neurones of the ganglia, may be separated from the mesenchymal cells without difficulty.

At this stage of development, the circulating blood cells are all derived from the blood islands of the yolk sac. Practically all of these cells are basophilic and polychromatophil primitive erythroblasts (fig. 1c) which were formed from the

FIG 1 — BRAIN OF A 12 DAY EMBRYO Photograph  $450\times$  (a) Endothelial cell (b) Neuro-epithelial cells (c) Polychromatophil primitive erythroblast (d) Hemocytoblast (e) Polychromatophil primitive erythroblast in mitosis FIG 2 — BRAIN OF A 13 DAY EMBRYO Photograph  $450\times$  FIG 3 — BRAIN OF A 14 DAY EMBRYO Photograph  $450\times$  (a) Perivascular mesenchymal cell (b) Endothelial cell (c) Orthochromatic primitive erythroblast of the circulating blood (d) Neuro-epithelial cells

mesenchyme in the yolk sac after passing through a hemocytoblast (myeloblast) stage<sup>1 2 3</sup> In this process almost all hemocyto blasts have developed into primitive erythroblasts so that only rarely does one find a hemocyto blast (fig 1d) in the circulating blood The erythroblasts continue to increase by mitotic proliferation primarily in the yolk sac vessels but also to a limited extent in the circulating blood (fig 1c)

The body mesenchyme at this time consists exclusively of loosely arranged outstretched mesenchymal cells, there is no evidence of formation of hemocyto blasts or histioid wandering cells (embryonic macrophages), nor is there any hematopoiesis The liver anlage is present, but as yet, manifests no hematopoietic activity The sole hematopoietic organ is the yolk sac, which is at this time the source of all the circulating blood cells of the embryo

*Thirteenth Day* Vascularization of the central and peripheral nervous system has progressed to such an extent that they are supplied with a rich net of anastomosing capillaries The cytologic differences between the endothelial cells and the spongioblasts (supporting cells) of the central nervous system have become more obvious But in the ganglia it is still impossible to distinguish many of the cells of presumed mesenchymal origin from many of the supporting cells of presumed neuro-epithelial origin The Schwann cells ensheathing the nerve roots are still indistinguishable from the surrounding mesenchymal cells

A significant change is observed in the neuro-epithelium of the central nervous system the cells have become much looser in arrangement especially around the vessels (fig 2) This is probably not artefact since it is constantly present in this location and is absent around blood vessels in other parts of the embryo including the ganglia It is the area in which Held's space will be located<sup>4 5</sup> Silver impregnation and Mallory-azan stains fail to demonstrate any reticular or collagenous fibers supporting the vessels at this stage of development

A new feature makes its appearance during the thirteenth or fourteenth day when perivascular mesenchymal cells (fig 3a) are observed along the vessels in the central nervous system As in all other processes, this ingrowth is always more advanced in the anterior than posterior part of the embryo The perivascular mesenchymal cells lie in close contact with the endothelium (fig 3b) between it and Held's space and so occupy the future Virchow-Robin space These cells are first seen along the entrance of the blood vessels into the central nervous system Occasionally a perivascular mesenchymal cell may be seen migrating into the central nervous system as evidenced by the fact that a part of the cell may be found in the central nervous system and the remainder in the surrounding mesenchyme There is no evidence that these cells are derived from the endothelial cells or the spongioblasts, or any of the cells of the circulating blood At this stage Mallory-azan stain and silver impregnation still fail to demonstrate the presence of reticular fibers around the vessels in the central nervous system

The perivascular mesenchymal cells (fig 3b) have a moderately basophilic somewhat vacuolated cytoplasm The nuclei have a heavily stained nuclear membrane and dark compact chromatin particles in a dark nuclear sap They are similar to

the histioid wandering cells (embryonic macrophages) of Maximow which have begun to develop heteroplastically from mesenchymal cells all through the body mesenchyme except that the latter have a more clearly demarcated cell border, a more coarsely vacuolated cytoplasm, and may be irregularly circular in outline instead of outstretched like the perivascular mesenchymal cells

At this stage active proliferation of primitive erythroblasts is still going on in the yolk sac sinuses. Rarely, basophilic definitive erythroblasts and hemocytoblasts may be found extravascularly in the yolk sac.<sup>1</sup> Most of the primitive erythroblasts in the circulation are in the late polychromatophil or orthochromatic stage (fig 3c). Hemocytoblasts (myeloblasts) are extremely rare in the circulating blood. Definite erythrocytopoiesis has begun in the liver. Most of the hematopoietic cells in the liver are hemocytoblasts or very young basophilic definitive erythroblasts. There is no sign of hematopoiesis in the diffuse mesenchyme of the embryo.

*Fourteenth Day* This period of development is marked by an increase in number of the perivascular mesenchymal cells so that almost all of the vessels in the central nervous system display a continuous layer of these cells. Typical histioid wandering cells are also found scattered in small numbers through the neuro-epithelium without any relation to blood vessels in the central nervous system.

The situation in the sympathetic and cerebrospinal ganglia is difficult to elucidate. The capillaries seem to lie directly against the supporting cells of the neuroblasts and only rarely are perivascular mesenchymal cells to be seen except at the edge of the ganglia near the mesenchyme. Here it is still impossible to separate the supporting cells of neuro-epithelial origin from the mesenchymal cells by any of the cytologic techniques used.

*Fifteenth Day* Hemocytoblasts are occasionally found extravascularly for the first time in the central nervous system and ganglia of the embryo. One may find isolated transitional stages between mesenchymal cells and perivascular mesenchymal cells and hemocytoblasts (fig 4a) and between the two former cell types and histioid wandering cells in various parts of the nervous system. The hemocytoblasts and histioid wandering cells are still found primarily in a perivascular location in the central nervous system and near the edge of the ganglia in the peripheral nervous system.

Identical heteroplastic formation of hemocytoblasts and histioid wandering cells is also present throughout the diffuse mesenchyme.

The origin of the erythrocytopoiesis in the central nervous system is easier to trace than in the peripheral nervous system because the erythroblasts are derived from the perivascular mesenchymal cells after passing through a hemocytoblast or histioid wandering cell stage, and because the perivascular mesenchymal cell may be clearly differentiated morphologically from the surrounding spongioblasts. However, in the ganglia the supporting cells of probable neuro-epithelial origin and the mesenchymal cells are so similar as to be hardly distinguishable on cytologic grounds (fig 4b vs c). In general, the mesenchymal cells have sharper, smaller chromatin, paler nuclear sap and larger nucleoli but in many instances these distinctions do not seem to be demonstrable and it is therefore sometimes

FIG. 4.—FIFTH CRANIAL GANGLION OF A 15 DAY EMBRYO. Camera lucida drawing 1800 X. (a) Transitional stage between a mesenchymal cell and a hemocytoblast (b) Neuro-epithelial cell (c) Mesenchymal cell (d) Intravascular orthochromatic primitive erythroblasts

maturation in the nervous system and body mesenchyme at the same level with respect to the anterior-posterior axis in any one embryo.

*Sixteenth to Twenty-first Day.* The precursors of the erythroblasts—the free stem cells (hemocytoblasts and histioid wandering cells)—have begun to transform into definitive erythroblasts (fig. 5c). Apparently all the hemocytoblasts in the nervous system differentiate into erythroblasts, but, as in the loose mesenchyme,<sup>6</sup> some histioid wandering cells remain scattered through the central nervous system.

The maturation of the erythroblasts of the nervous system is entirely similar to that of erythroblasts in the embryonic liver and mesenchyme, and embryonic and adult bone marrow. They are all of the definitive erythroblast series in contrast to the primitive erythroblasts which were formed intravascularly in the yolk sac only<sup>1, 2, 6</sup> and which are the first circulating blood cells of the embryo (figs. 1-5). The more immature basophilic erythroblasts have rather large acidophil nucleoli

and a small amount of chromatin in large vesicular nuclei surrounded by densely basophilic cytoplasm (fig 5c) In the course of maturation the large nucleoli break down into many smaller ones, the chromatin particles begin to assume a checker board pattern and the cytoplasm becomes less basophilic so forming the poly

FIG 5 — LAMINA TERMINALIS OF A 16 DAY EMBRYO Camera lucida drawing 2200 X (a) Neuro-epithelial cells (b) Hemocytoblast (c) Immature definitive basophilic erythroblast (d) Intravascular orthochromatic primitive erythroblast

chromatophil and orthochromatic erythroblasts (figs 5 and 6) Under the low power the nuclei of the latter appear quite dark (fig 7a) Mitoses are quite frequent (fig 6c)

At this stage the erythroblasts may superficially resemble the supporting cells of the nervous system The latter have more delicate chromatin particles, darker

FIG. 6—THORACO-LUMBAR SYMPATHETIC GANGLION OF A 16 DAY EMBRYO. Camera lucida drawing 1800 $\times$ . (a) Neuroblast (b) Polychromatophil definitive erythroblast (c) Polychromatophil definitive erythroblast in mitosis (d) Satellite cell of neuro-epithelial origin

Aggregates of erythroblasts are always found in certain characteristic locations in the nervous system (figs 5, 6 and 7) and sporadically in almost every part of the nervous system. Relatively large foci of erythroblasts are invariably encountered in the lamina terminalis (figs 5 and 7) of the central nervous system.

Smaller foci are found in the thalamus and ventral portions of the cerebral hemispheres. Small foci of erythroblasts are also found all through the rest of the brain and to a very limited extent in the spinal cord. Erythrocytopoiesis is common in the cerebrospinal ganglia, especially anteriorly. Occasional foci are present in the roots of the cerebrospinal and sympathetic ganglia. Large masses of erythroblasts are invariably encountered in the thoraco-lumbar sympathetic ganglia, in some cases even outnumbering the cells of neuro-epithelial origin (fig. 6). Erythrocytopoiesis is rare in the peripheral ganglia in the intestinal tract.

The further development of this erythrocytopoiesis in the nervous system is difficult to trace. During the eighteenth and nineteenth days of development the erythroblasts in the nervous system disappear entirely. At this time collections of degenerating cells are found in the central nervous system corresponding to the

FIG. 7.—LAMINA TERMINALIS OF AN 18 DAY EMBRYO. Photograph 300 X. (2) Focus of erythroblasts.

location of the erythroblasts but, since foci of spontaneous degeneration of the neuro-epithelial and other cells are so common in intrauterine life, it is impossible to determine whether the cells undergoing spontaneous degeneration in the nervous system are solely of neuro-epithelial or of mixed origin.

#### DISCUSSION

The first investigators to stress the hematopoietic potentialities of the mesenchymal cell in localities other than the commonly recognized hematopoietic sites in the embryo were Saxer<sup>3</sup> and Maximow.<sup>4</sup> In 1909 Maximow emphasized the ability of the mesenchymal cell, not only in the areas as yolk sac and liver which are commonly accepted as hematopoietic organs, but all through the diffuse body mesenchyme to develop into free multipotent cells and to give rise to the various blood cells.

Since then, Maximow's concept of the multipotentialities of the mesenchymal cell has been substantiated by numerous reports in which hematopoiesis has been demonstrated in various locations in the normal mammalian embryo, chorionic villi,<sup>9</sup> the loose connective tissues,<sup>10</sup> breast tissue,<sup>11</sup> testes,<sup>1</sup> sole of the foot<sup>12</sup> and prostate.<sup>13</sup> In the lower vertebrates, the kidney, gonads, and intestinal tract are the site of hematopoiesis in adult animals.<sup>14</sup> In fish Scharrer<sup>15</sup> has described hematopoiesis in the meninges in the form of a definite organ of myeloid tissue in much the sense of mammalian marrow. Hematopoiesis has been seen in all of these areas in the present study in the embryonic rat.

It would appear from these studies in the lower vertebrates and in mammalian embryos that the mesenchyme at some time in embryonic or postnatal life is hematopoietic throughout most of its distribution. Furthermore, studies on embryonic tissues stimulated by infection,<sup>16</sup> toxins<sup>17</sup> and transplantation<sup>18</sup> have demonstrated that the potencies realized during normal embryonic life do not represent the sum total of mesenchymal potentialities of differentiation. By means of these experimental approaches, it has been shown that various localities, which, in embryonic life are not hematopoietic, or only slightly so, may become the site of active blood formation, or that the number of any cell type produced may be augmented or decreased.

Similarly, in syphilitic embryos and in embryos with erythroblastosis fetalis, active erythrocytogenesis may persist in the liver long past the usual time in normal human embryos. Miller<sup>19</sup> has described erythrocytogenesis in the heart and stomach of infants of prediabetic mothers.

However, in spite of this remarkable hematopoietic ability of the mesenchyme, there has been little evidence of any hematopoiesis in the central or peripheral nervous system in embryos or adults in any vertebrate. Gilmour,<sup>10</sup> in humans, described erythroblasts about the nerves in the meninges. This is very common in the rat embryo. Gutsell<sup>20</sup> illustrated an island of myeloid tissue in a peripheral nerve of a newborn infant. Collin and Baudo<sup>21</sup> and also Watrin<sup>22</sup> described erythropoiesis in the glandular (anterior?) lobe of the pituitary. However, since there were no illustrations and since the morphology of the cells they described was not characteristic of erythroblasts it is probable that they were describing cells with pyknotic nuclei in areas of spontaneous degeneration. The demonstration of hematopoiesis in the central and peripheral nervous system in this study, therefore, serves to substantiate still further the concept of the mesenchyme as having hematopoietic potentialities in all organs in whose structure it participates.

Since Rio-Hortega<sup>23</sup> separated the microglia from the other glial cells of the nervous system, there has been some controversy concerning the origin of these cells. Metz and Spatz<sup>24</sup> have traced them to spongioblasts and have summarized the evidence in favor of a neuro-epithelial origin. Rio-Hortega and a majority of workers have derived microglia from the mesenchyme. Since it is universally accepted that erythroblasts and hemocytoblasts are of connective tissue origin, the present study demonstrates that cells of connective tissue origin have entered into the neuro-epithelium in embryonic life. It is conceivable that some of these mesenchymal cells may serve as a source of microglia, the macrophages of the

nervous system, just as they serve as a source of histioid wandering cells, the macrophages of the embryonic connective tissues. This hypothesis receives further support because of the close relationship if not morphologic identity of the microglia of central nervous system and the macrophages of the connective tissues.<sup>11</sup>

The present study has failed to demonstrate penetration of the embryonic central nervous system by cells of mesenchymal origin except by migration along blood vessels. It is of interest that Von Santha and Juba,<sup>16</sup> employing Hortege silver carbonate impregnations of the nervous system in the embryonic rat, failed to demonstrate any mesenchymal invasion of the central nervous system other than by mesenchymal cells migrating along the blood vessels.

### CONCLUSIONS

1. Definitive erythropoiesis in the central and peripheral nervous system is a normal occurrence in the embryonic rat.

2. This is of significance because it is an illustration of the hematopoietic potency of the embryonic mesenchyme in an area where it has not been previously described.

3. It is of significance also because it presents unequivocal proof of the presence extravascularly of cells of connective tissue origin in the central nervous system. It is possible that some of these cells may serve as the precursors of the microglia.

4. There is no evidence that cells of connective tissue origin enter the central nervous system in any way except by migrating in along blood vessels.

### ACKNOWLEDGMENT

I wish to acknowledge the helpful criticisms of Dr. William Bloom of the Anatomy Department of the University of Chicago in whose laboratory the major part of this work was done.

# PATHOLOGY OF THE RUPTURED SPLEEN IN ACUTE VIVAX MALARIA

By JOSEPH M. LUBITZ, M.D.

**D**ESPITE the fact that malaria is a worldwide disease involving millions of individuals and considering the large number of cases seen in military service, spontaneous rupture of the spleen is actually a rare occurrence. Seventy-two cases were accumulated by Leighton prior to 1917 and 64 cases have been reported subsequent to this date.<sup>1</sup> Studies of the pathology of malaria are of importance in those parts of the world where malaria is prevalent. Previous pathologic descriptions of the spleen in acute tertian malaria in man have been sketchy. Furthermore, the mechanisms underlying the rupture have not been adequately studied. A pathologic description of the spleen in 4 cases of acute tertian malaria is therefore pertinent even though the incidence of malarial attacks and possibility of splenic rupture is rapidly decreasing. In 3 of the 4 cases under consideration, spontaneous rupture had occurred. The fourth case was that of a subcapsular hemorrhage, presumably just prior to rupture. All cases were successfully operated with splenectomy.

## PATHOLOGIC FINDINGS IN SPONTANEOUS RUPTURE IN ACUTE MALARIA

The pathology of the spleen in acute malaria has been described by Taliaferro and Mulligan<sup>2</sup> and by Ash and Spitz.<sup>3</sup> Of the 64 cases reviewed by us, only 29 included gross pathologic descriptions. These are summarized as follows. Grossly the spleen is enlarged with an average weight of 450 to 500 Gm. The consistency is soft, the color is reddish rather than slate gray as occurs in chronic malaria. Rupture may occur on any surface of the organ. It may be explosive or with multiple rents but in the majority of cases there is only one tear. The size of the tear varies from a small nick to 10.0 cm. A subcapsular hematoma is most probably the initial stage preliminary to the rupture.

In 16 of the 29 cases, microscopic descriptions were reported. These changes are essentially that of the pathologic changes of the spleen occurring in acute malaria in man and animal. Characteristic changes in the spleen are both cellular and vascular. Three distinctive features of the cellular changes are found:

*Cellular Changes* 1. *Phagocytic Activity* Macrophages proceed to remove by phagocytosis malarial pigment and disrupted erythrocytes. The heterophiles and lymphocytes play an insignificant part. The reticulum cells display the most prominent activities. These cells within the splenic cords become numerous, enlarged, predominating in the cellular picture of the spleen. Within the venous sinuses these macrophages can be seen engulfing not only the yellowish green pigment of the parasites, but also the red cells or hemoglobin derivatives. In the dilated splenic

Department of Pathology, Veterans Administration Center, Wood, Wisc., and Marquette University School of Medicine, Milwaukee, Wisc.

within the widened splenic cords. They contained both blood pigment and malarial pigment granules. The endothelial cells were hyperplastic projecting into the lumen or desquamated into it. The dilated sinusoids contained desquamated endothelial cells few red cells scarce polymorphonuclear cells and large single and multinucleated macrophages containing iron and malarial pigment. The cellular mass lay close to the vessel wall often merging with the cord cells forming a thrombus. Veins and venules were frequently dilated forming pools containing the same cells that were seen in the sinusoids. In the subendothelial zone there was a layer of macrophages and monocytes containing pigment. In many portions of the spleen but particularly under the capsule not necessarily at the site of rupture there were large dilated veins and sinusoids which were thrombosed. The thrombus was comprised of a matrix of fibrinous material in which there were macrophages, hemolyzed and degenerating red cells and polymorphonuclear cells. Plasmodia could not be identified in the fixed tissue sections using the bismarck, toluidine and eosin or Romanowsky's stains. Scrapings from the spleen showed rare *P. vivax* within the red cells but not within the macrophages.

CASE II (Lap 90874) A 36 year old male who had served in New Guinea, Philippine Islands and Japan returning to the States one year previously was admitted to the hospital complaining of abdominal pain. He had had no attack while overseas and had been under atabrine prophylaxis. On physical examination the abdomen was tense. Tenderness was localized to the left upper quadrant. Dullness in the left lower lobe of the lung indicated pleural fluid. The admission red count was 2,600,000 hemoglobin 8.5 Gm. WBC 4850 temperature 101.4 degrees. X-ray examination indicated an enlarged spleen. *P. vivax* was found on blood smear and antimalarial treatment was started. It was not felt that splenic rupture had occurred but he was closely observed. On the ninth day he was operated. At surgery (Dr. Dwight Fishwick) a large amount of old dark blood was found in the peritoneal cavity. The spleen with a large subcapsular hematoma was found adherent to the diaphragm and walled off by omentum. Splenectomy was done. On the fifteenth day the lesion in the left lower lung was still present. The red count and temperature returned to normal and the patient was discharged. At the time of discharge blood count, temperature and white count were normal.

Gross (Fig. 1) The spleen weighed 400 Gm. measured 15.0 x 12.0 x 5.0 cm. Only at the hilus was the capsule intact. On the other surfaces the capsule was completely stripped from the splenic pulp by a large subcapsular blood clot measuring 9.0 x 7.0 x 1.0 cm. On the upper pole of the convex surface of the spleen there was an irregular rent measuring 2.0 cm. in diameter and 5.0 mm. in depth. On the opposite pole there were small irregular holes in the splenic tissue. Cut section revealed a soft purplish red pulp with a bulging parenchyma.

Microscopic The follicles were large with hyperplastic germinal centers in which there were few mitoses. The follicles were fairly well outlined against the red pulp. In the red pulp the splenic cords were thickened. reticulum cells were moderately hyperplastic. The sinusoids were poorly outlined. No malarial pigment was seen. Eosinophilic cells were present. The endothelial cells were moderately hyperplastic. In the trabecular veins there was a subintimal cushion of cells similar to those seen in the splenic cords. A thick layer of cells of similar type was found between the adventitia and muscularis. The vessels and sinusoids were often dilated and contained an admixture of cells with fibrin closely aligned to the wall. Small hemorrhages were seen deep under the capsule. No parasites could be identified in the tissues or the smears of the splenic pulp.

CASE III (Ric 84240) A 30 year old male was admitted to the hospital complaining of chills, fever, vomiting and malaise. He had served in New Guinea and had experienced several attacks of malaria in the past. The initial blood smear was positive for *P. vivax*, red blood cells 3,400,000, white blood count 12,600. During the afternoon of the day of admission he suddenly fainted. He recovered with pain in the epigastrium and then lapsed into shock. On physical examination there was guarding of the abdominal muscles and tenderness over the abdomen. The spleen was not felt. At surgery (Dr. John G. Slaney) the peritoneal cavity was found to be filled with bright red blood which was oozing from the spleen. The spleen was removed. Postoperatively there were no complications and the red count returned to normal.

Grossly the spleen weighed 255 Gm. and measured 14.0 x 8.0 x 4.5 cm. Over a distance of 9.5 x 7.0 cm. the capsule had been torn away from the surface. On the convex surface there was a small rent in

the splenic tissue measuring 50 mm. On section the splenic pulp was dark brown in color soft with prominent lymph follicles.

*Microscopic.* The follicles were hyperplastic with active germinal centers. The periphery of the follicles fused with the cellular red pulp. In the latter the splenic cords were thickened and the reticulum cells enlarged. The sinusoids were poorly defined and filled with macrophages. No malarial pigment granules or parasites were seen. The trabecular veins, venules and sinusoids were often dilated either empty or engorged with macrophages, red cells and polymorphonuclear cells. In the subintima and adventitia there was a layer of cells similar to those found in the cords. No thrombi were noted. Under the capsule there was a large hemorrhage which extended deep into the pulp. Smears from the splenic pulp were positive for *P. vivax* within the red cells. In one remote area in which the overlying capsule was intact numerous dilated venules were present filled with hemolyzed blood, red blood cells and white blood cells.

FIG. 1.—Case II. Spleen gross. Denudement of capsule and blood clot.

**CASE IV (And 90495).** A 22-year-old white male was admitted to the hospital with vague abdominal pain of sudden onset, chills and fever. He had served in the Southwest Pacific. While in Guadalcanal he had experienced several attacks of malaria. His last episode was in this country one year previously. His present illness began twelve hours before admission with chills and fever. As he had been a returned patient in the past, he took atabrine for what he considered to be another attack of malaria. On physical examination there was a splinting of the abdomen and pain in the upper abdomen on deep respiration. In the left lower lung breath sounds were slightly impaired. A ray showed slight opacity of the left lower lobe. Blood smears for malaria were repeatedly negative. While in the hospital pain gradually developed in the left upper quadrant, spreading to the lower half of the abdomen with increasing intensity. Admission temperature was 100.8 F., red count 4,950,000, hemoglobin 14.5 Gm., white count 12,000. During the next few days the patient became toxic, listless, and acutely ill. At no time was the spleen palpable. Since the pain was not fully localized and smears were repeatedly negative for parasites,

FIG 2.—Case IV Spleen gross Indentation of capsule underneath which there is a subcapsular hematoma

FIG 3.—Case IV Spleen microphotograph (low power) Showing well defined subcapsular hematoma

th diagnosis was held in abeyance and he was further observed. However a diagnosis of ruptured malarial spleen being suspected it was considered advisable to explore him on the sixth day following hospitalization. At surgery (Dr. James Sullivan) the spleen was found to be about double its size. There was perisplenitis but no hemorrhages were seen. The spleen was removed.

*Gross* (Fig. 2) The spleen weighed 300 Gm. and measured  $13.0 \times 9.0 \times 4.0$  cm. The capsule was dull and covered with fibrinous shreds. No rent or hemorrhage was seen on external examination. On cut section, on the convex surface a localized subcapsular hemorrhage measuring 5.0 mm. was found under a small indentation of the capsule. The parenchyma was brownish red in color and dripping. The follicles were small but prominent.

*Microscopic.* The capsule was slightly thickened, the serosal cells hyperplastic and covered with fibrin. The area seen grossly as hemorrhage was found to be well defined (fig. 3). Nearby were smaller diffuse hemorrhages. All sinusoids under the capsule were severely engorged with blood. An occa-

Fig. 4—Case IV. Spleen, microphotograph (high power) of an area remote from subcapsular hematoma. Fibrinous perisplenitis, cellular hyperplasia and dilated sinusoids engorged with blood.

sional dilated sinusoid or vein was filled with erythrocytes, particularly under the capsule at sites remote from the hematoma (fig. 4). The follicles were prominent with active germinal centers showing large reticulum cells with mitoses. Nuclear fragments were not seen. The margin of the follicles merged imperceptibly into the cellular red pulp. The thickened splenic cords contained numerous reticulum cells which were somewhat elongated but not as vesicular as found in previous cases. The endothelial cells were hyperplastic and rounded. The sinusoids were collapsed and devoid of erythrocytes. They contained however numerous large pale cells resembling reticulum cells, many of which contained occasional polymorphonuclear cells and rarely multinucleated cells.

#### Discussion

A review of the literature indicates that malaria is the most common single cause of spontaneous rupture of the spleen. Smith and Custer<sup>1</sup> found no cases of

as Spleen, spontaneous rupture, in the records of the Army Institute of Pathology. Of these, 22 were recurrent malaria, 7 infectious mononucleosis, 5 Banti's disease, 2 leukemia, 3 torsion, and 5 cause unknown. Of the 64 reported cases reviewed in the literature up to 1946,<sup>1</sup> 25 were in naturally acquired malaria and 39 in inoculation malaria. The incidence of spontaneous rupture in induced malaria is higher than in acquired malaria. The age of the patient, the repeated paroxysms of malaria without specific therapy, and the failure to recognize the symptoms of rupture probably account for the higher mortality from rupture of the spleen in the induced group. In the chronic stage of malaria, rupture of the spleen is rarely described in this climate. However, rupture by minimal trauma in malarious zones is frequent. *P. vivax* is the most common infecting agent, although other species of plasmodia have been described.

The mechanism of rupture is probably three-fold: (1) increase of intrasplenic tension due to cellular hyperplasia and engorgement, (2) compression by abdominal musculature, (3) local lesions due to vascular occlusion. Rigdon's hypothesis of obstruction of the vessels by hyperplasia is supported by our findings. His findings

TABLE 1—*Histopathology of Spleen in Acute Malaria*

Case		Cellular infiltration		Sinuses			Reticulum hyperplasia	Active germinal centers	Dilated veins and venules	Thrombosis	Infarction	Subcapsular hemorrhages
		Veins	Capsule	Hyperplastic endothelium	Obstruction	Dilatation						
1	11948	+	—	+	+	+	+	+	+	+	+	+
2	90874	+	—	+	+	+	+	+	+	—	—	+
3	84240	+	—	+	+	+	+	+	+	—	—	+
4	90495	+	—	+	+	+	+	+	+	—	—	+

in experimental animals are identical with those observed in humans. He believes that reticular and endothelial hyperplasia obstructs venules and sinuses resulting in thrombosis and infarction which cause interstitial and subcapsular hemorrhages. Subcapsular bleeding strips the capsule resulting in further hemorrhage with distention of the capsule and final rupture. In all four cases (table 1) a common finding was the presence of dilated sinuses and hemorrhages immediately under the capsule. Although infarctions have been frequently described in animals,<sup>6</sup> in only 1 of our 4 cases was infarction found. It alone, therefore, cannot be the sole cause of rupture.

Subintimal and periaventricular leukopoiesis is of special interest and is a striking finding. This appears to be a reversion to embryonal potency. Such leukopoiesis also occurs in cases of infectious mononucleosis.<sup>8</sup> One such case described by Sullivan and Wassermann<sup>7</sup> was available for study. It, too, showed extreme hyperplasia but the hyperplastic cells were typically infectious mononucleosis cells rather than the histiocytic cells seen in malaria. Jaffé and others<sup>8</sup> have described similar changes in acute leukemia with leukemic cells in the walls of the vessels. Smith and Custer discuss the histopathologic changes of ruptured spleen in infectious mono-

nucleosis. They found changes which closely resemble those seen in malaria, such as blurred pattern representing general hyperplasia, cellular subintimal infiltration in arteries, veins, trabeculae and capsule. It differs from the malarial cases which we have studied in failure of leukopoiesis to occur in arteries, absence of dilated veins, thrombosis or infarction in infectious mononucleosis. Thus, from the reported cases of infectious mononucleosis and from failure to find infarction and thrombosis in three of the four cases studied, it can be concluded that these vascular changes alone are not necessary for rupture to occur. Smith and Custer noted dissolution of the capsule and trabeculae due to cellular infiltration and edema. They believe that rupture was due to a rapidly expanding organ with damage of the enveloping framework. From our studies it would seem that dilated sinuses and small subcapsular hemorrhages occurring in the malarial spleen are important factors, initiating the hematoma. We agree with Smith and Custer that a subcapsular hematoma must occur prior to rupture. The subcapsular hemorrhage described in Case IV probably represents this stage. Under sufficient tension due to the general cellularity and frequently by additional pressure due to minimal trauma, this hemorrhage may rupture through the capsule.

Referred pain from the diaphragm to the shoulder via the phrenic nerve has been described in 6 cases of ruptured malarial spleen. It has also been commented on in ruptured spleen due to infectious mononucleosis. However, perhaps more significant is the presence of irritation of the left lower lobe of the lung. This elicits impairment of breath sounds, dullness, and opacity by x-ray examination. In Cases II and IV pleural fluid was diagnosed before surgery. In the previously cited case of infectious mononucleosis by Sullivan and Wassermann,<sup>7</sup> pleural fluid was also noted before surgical intervention. In 3 cases of spontaneous rupture of the spleen reported by Littenfield,<sup>9</sup> pulmonary complications developed in the left lung field. However, they noted this only following surgery. This pleural irritation is probably due to perisplenitis with transmigration of toxic irritants through the diaphragm. In cases in which a diagnostic problem is presented, this sign may be of value.

#### SUMMARY

1. Opportunity to study the pathologic changes in ruptured spleen of acute vivax malaria was afforded by splenectomy.
2. Subcapsular hematoma precedes rupture.
3. The capsular tear is an obvious consequence of the changes in the spleen occurring in acute malaria. Small hemorrhages occur in the vicinity of the capsule or deep in the tissues.
4. A rapidly enlarging spleen with underlying vascular alteration predisposes to rupture. Minimal trauma may be a precipitating element.
5. Diffuse cellular hyperplasia, subintimal and adventitial leukopoiesis, dilated sinuses and occasional thrombosis and infarction constitute the characteristic pattern in malaria.
6. Changes in the left lung base may serve as a diagnostic aid in cases in which the diagnosis of splenic rupture is considered.

## HEMATOPOIETIC TISSUES

EFFECTS OF FOLIC ACID DEFICIENCY AND A FOLIC ACID ANTAGONIST ON CHICKS. *E. Wolf* From the Research Department Lederle Laboratories Pearl River N. Y. Arch. Path. 46 559-566 1948

Rapidly growing subjects like newly hatched chicks readily lend themselves for such purposes as the study of nutritional disturbances. It was for this reason that they were selected for experiments in folic acid deficiencies. About 200 one day old New Hampshire Red chicks were divided equally into the following six dietary groups: control; folic acid free diet; folic acid free diet plus folic acid by injection; regular diet plus 4 aminopteroylaspartic acid in the diet; regular diet plus 4 aminopteroylaspartic acid by injection; and folic acid free diet for ten days followed by same diet supplemented with a daily intraperitoneal injection of 0.1 mg. of folic acid. Changes in the folic acid-deficient birds and those in the birds treated with antagonist were essentially the same. Of the organs involved, the bone marrow and bowel showed the greatest departure from normal. The ultimate picture of the marrow was that of a severe aplasia with a myxomatous appearance of the connective tissue. In the distal third of the small bowel there was an atrophy of the mucosa with the appearance of retention cysts and fibrous elements of the stroma. Folic acid will prevent these changes when injected into folic acid-deficient animals. O. P. J.

HISTOPATHOLOGIC OBSERVATIONS IN CASES OF HODGKIN'S DISEASE TREATED WITH NITROGEN MUSTARD. *V. H. Cornell and A. S. Blau* From the Laboratory Service, Walter Reed Hospital, Washington D. C. Am. J. Path. 25 233-237 1949

Clinical response to the use of intravenous nitrogen mustard in diseases of the lymphatic system has been reported by various authors since 1944. In order to determine possible differences in lymph node architecture before and after therapy, 17 cases from a series of 55 were selected for study. The most surprising thing was the absence of a single criterion that could be said to exist in any two treated cases. The authors point out that it is difficult to rationalize the use of a drug which primarily attacks the lymphocytes in the treatment of a disease generally considered to be one of the reticuloendothelium. O. P. J.

EFFECT OF CONTINUOUS RADIATION ON CHICK EMBRYOS AND DEVELOPING CHICK. II. BONE MARROW LYMPHOID TISSUE AND PERIPHERAL BLOOD. *S. Warren and J. F. J. Dixon* From the Laboratory of Pathology of the Harvard Cancer Commission, Boston, Mass. Radiology 53 669-670 1949

By means of radioactive phosphorus ( $P^{32}$ ) the effects of lethal and sublethal irradiation on the bone marrow were studied in chick embryos and developing chicks. There was an overall retardation of the growth of the birds; a marked retardation of bone growth and especial sensitivity was noted in the skeletal system and ovaries. In the present paper the effects on bone marrow, lymphoid tissue and peripheral blood are recorded.

In the bone marrow the effects were the result of the heavy irradiation of marrow cells and the concentration of  $P^{32}$  within the bones. Sublethal irradiation resulted in a marked retardation of the growth of the birds.

poietic cells and a reduction of mitotic activity so that pancytopenia developed maximally in 1 to 2 weeks. In 2 to 3 weeks recovery began with an increase in mitotic activity and later maturation of the blood cells. When irradiation was lethal there was a complete halt of mitotic activity and of maturation within 2 to 3 days after use of  $P^{32}$  with resultant hypoplasia of the marrow, fatty degeneration within the marrow and progressive pancytopenia with death in 2 weeks. In both lethal and sublethal actions the reticulo-endothelial cells were little affected and tended to give rise to primitive blood cells during recovery.

In lymphoid tissue  $P^{32}$  caused suppression of mitoses and a thinning out of the lymphocytes. This response was followed rapidly by prompt and marked regeneration of lymphoid tissue with recovery being complete in most instances. Regeneration was excessive in amount.

In the peripheral blood the lymphocytes fell rapidly and with recovery returned fairly rapidly to normal. The granulocytes fell more slowly; an agranulocytosis was present within 2 weeks and the recovery phase was slower than for the other blood cells. The red cells fell quite slowly following a lag period and recovery was quite rapid although slower than the return of the lymphocyte level to normal. S. E.

**INFLUENCE OF LOCAL ACIDIFICATION OF TISSUE BORNEING CANCEROUS GROWTHS WITH SPECIAL REFERENCE TO THE EOSINOPHIL, THE PANETH CELL AND THE ACIDOPHILIC PLASMA CELL.** C. E. Black and R. S. Ogle

From Department of Pathology, Sparrow Hospital, Lansing, Mich. Arch. Path. 46: 107-118, 1948

Eosinophils, Paneth cells and acidophilic plasma cells are usually more numerous in the lamina propria of the small intestine than they are in either the stomach or large bowel. Collections of acidophilic cells which are usually in the vicinity of cancerous growths seem to be a defensive response of the host. Acidophilic cells are seldom the source of primary neoplasm. There may be some relationship between the presence of these cells in the small intestine and appendix and the infrequency of carcinoma or tendency slowly to metastasize there.

O. P. J.

**THE RATE OF MITOTIC ACTIVITY IN THE LYMPHOID ORGANS OF THE RAT.** E. Andreassen and S. Christensen

From the Department of Anatomy, Faculty of Medicine, University of Copenhagen, Denmark. Anat. Rec. 103: 401-412, 1949

In studies of mitotic activity with sectioned material of lymphoid tissue the results have not been wholly reliable because of the irregular and capricious distribution of dividing cells. In an effort to determine the proportion of dividing cells visible in a population, suspensions of cell nuclei were made by treating finely divided tissue with 5 per cent citric acid for one half to one hour. After a series of centrifugations, staining with galloxyaniline, resuspensions in absolute alcohol and finally benzyl benzoate, ten thousand nuclei were counted in a Bürker-Türk counting chamber. Mitotic phases before the disappearance of the nuclear membrane and after reconstruction of the nuclear membrane in telophase were rarely seen. Hence the counts involved phases between these two extremes. Thymic lymph nodes and spleens were examined from rats of three different age groups: 1 c, 1 month, 3 months and 8-12 months old. The number of mitotic figures per thousand nondividing nuclei was consistently higher in the thymus than in either lymph nodes or spleen. There was a decrease with age which was more noticeable in lymph nodes and spleen. Additional experiments were conducted to determine the source of lymphocytes in rats during restitution after starvation. The thymus reaches its normal mitotic activity 3-4 days after restitution while lymph nodes and spleen show no deviation from normal either at the end or during restitution. O. P. J.

**CHANGES IN THE CAPSULE OF THE LYMPH NODE IN EXPERIMENTAL HYPERPLASIA.** W. J. Furness

From the Department of Anatomy, University of Illinois College of Medicine, Chicago, Ill. Arch. Path. 47: 273-282, 1949

Lymph node hyperplasia is a common occurrence in some blood dyscrasias and under certain experimental conditions. Attention has been generally directed toward structural changes of the lymphatic tissue and not of the capsule. In order to study the latter, experimental hyperplasia was produced in hamsters and rats by injecting Eberthella typhosus vaccine. Hyperplastic mediastinal and bronchial lymph nodes from calves with acute bronchopneumonia were obtained from the slaughter house. In

hamsters and rats hyperplastic nodes had a portion of the cortex extending through areas deficient in capsule because of a previous rupture. Maximal peripheral expansion of these nodes was observed in the hilar region. The degree of extracapsular migration of lymphatic tissue into the perinodal areolar tissue increased with the length of the postinjection period. In the hyperplastic calf lymph node the capsule did not rupture because of its thickness.

## ERYTHROCYTE PHYSIOLOGY

INFLUENCE OF ENDOCRINE FACTORS ON HEMOPOIESIS IN THE ADULT FROG, *RANA PIPIENS*. E T Bossak, A S Gordin, and H A Charipper. From Department of Biology, Washington Square College, New York University, New York, N Y. *J Exper Zool* 109: 13-31, 1948.

The hormonal control of erythropoiesis has been investigated in the mammal and bird but not in the amphibia. The adult frog normally has hypoplastic marrow during hibernation so that perhaps the posthibernation erythropoiesis may be the result of participation by the endocrine system. Adult frogs of both sexes were kept in refrigerators at a constant temperature of 4-6°C before and during the experiment. Four groups of test animals received 20 injections of sesame oil, thyroxine, testosterone propionate, and estradiol benzoate respectively. The animals were sacrificed 45 days after start of injections. The results indicate that there is some relationship between the endocrine system and hemopoiesis but further study is necessary in order to understand the mechanism.

O P J

ON THE NATURE AND SIGNIFICANCE OF STIPPLING IN LEAD POISONING WITH REFERENCE TO THE EFFECT OF SPLENECTOMY. A J S McFadzean and L J Davis. From the University Department of Medicine, Royal Infirmary, Glasgow, Scotland. *Quart J Med* 18: 57-72, 1949.

In both human patients and in guinea pigs with lead intoxication stippling is demonstrable in the bone marrow in normoblasts as well as in the non-nucleated erythrocyte in marrow and peripheral blood. A positive reaction for iron is exhibited by a variable proportion of the granules and there is often associated evidence of defective hemoglobinization in the affected cells. It is of interest that in the experimental guinea pigs employed in these studies splenectomy ameliorated or prevented the anemia of lead intoxication as well as increased the relative proportion of stippled cells in the circulation and the frequency of a positive reaction for iron in the granules. The suggestion is made that lead interferes with hemoglobin synthesis with partial failure in the incorporation of iron into the protoporphyrin ring. Removal of the more defective cells by the spleen could thus explain the hemolytic component of lead intoxication and the beneficial effect of splenectomy on experimental lead-induced anemia. It is possible that a similar mechanism may explain the beneficial results of splenectomy in a peculiar acquired hemolytic anemia previously described by the authors in which iron-containing inclusion bodies were demonstrated in the erythrocytes (*Glasgow M J* 28: 237, 1947).

W N V

THE RATE OF LOSS OF POTASSIUM FROM HUMAN RED CELLS IN SYSTEMS TO WHICH LYSINS HAVE NOT BEEN ADDED. E Ponder. From the Nassau Hospital, Mineola, Long Island, New York. *J Gen Physiol* 35: 461-479, 1949.

In previous studies on the human red cell the loss of K increases with time until the K concentration inside the cell is approximately the same as that in the medium outside in systems containing lysins. When no lysin has been added the losses are rapid at first and they tend to slow down so that a new steady state remote from equilibrium is reached. The present experiments concern four such kinds of

systems (1) Washed red cells in saline at 4 C (2) washed red cells in saline at 25 C (3) washed red cells in saline at 37 C and (4) washed red cells in systems at 4 C 25 C, and 37 C containing hypotonic saline glucose or a number of other substances. In order to prevent bacterial contamination and thereby possibly introduce a hemolysin, all of the experiments were conducted under aseptic conditions based on the method used by Osgood for marrow culture

OPJ

THE RELATIVE RATE OF PENETRATION OF THE LOWER SATURATED MONOCARBOXYLIC ACIDS INTO MAMMALIAN ERYTHROCYTES *J W Grinn* From the Physiological Laboratory, Princeton University Princeton N J *J Cell & Comp Physiol* 33 247-266 1949

Since the work of Overton it has been widely accepted that compounds soluble in lipid solvents penetrate cells by reason of their solubility in the lipids of the cell surface. A new method was devised to measure the relative rate of penetration of the lower fatty acids into mammalian erythrocytes. This method, a chemical one, depends upon the fact that oxyhemoglobin loses some of its oxygen when placed in an environment containing an increased hydrogen ion concentration. The relative rates of penetration of the fatty acids investigated were found to be (a) for beef cells: caprylic < heptylic < caproic = valeric = butyric > propionic > acetic > formic (b) for human cells: caprylic = heptylic < caproic < valeric > butyric > propionic > acetic > formic. The rates of hemolysis by these acids were determined and found to be (a) for beef cells: caprylic > heptylic > caproic > valeric < butyric > propionic > acetic < formic (b) for human cells: caprylic > heptylic > caproic < valeric < butyric > propionic > acetic < formic.

OPJ

CRYPTOGENIC METABOLISM OF ERYTHROCYTES *L Heilmeyer and Th Eilers* From the Medical Clinic of the University of Heidelberg Schweiz med Wschr 78 975-76 1948

In an investigation of the metabolism of hemoglobin in pernicious anemia, the quantity of eliminated urobilin was found to be essentially higher than the reticulocyte level would indicate. By adding Giemsa stain for 8-12 hours in the refrigerator to the usual staining of reticulocytes with brilliant cresyl blue, pathologic reticulocytes of crescent form and containing many vacuoles are brought in evidence. These forms are not visible when the smears are stained in the usual way. They are more frequently found in smears from the spleen than in the peripheral blood. These reticulocytes are believed to be destroyed particularly fast within 24 to 48 hours. Even if they do not contain the final hemoglobin, they possibly represent prestages causing the increased metabolism of urobilin.

C.M

ESTIMATION OF RELATIVE CORPUSCLE AND SERUM VOLUMES IN BLOOD BY VARIOUS APPLICATIONS OF THE DILUTION PRINCIPLE. *P L McLain and C H W Rube* From the Departments of Physiology and Pharmacology, University of Pittsburgh School of Medicine, Pittsburgh Pa. *Am J Physiol* 156 12-18 1949

It has long been recognized that centrifugal methods do not completely separate corpuscles from plasma. Attempts to measure the amount of fluid left in the sediment have not given constant results. These measurements have usually been based on some application of the principle of serum or plasma dilution. The present study was done on whole beef blood. Relative corpuscle and serum volumes were estimated by 12 different applications of the serum dilution principle. These results were then compared with those obtained by centrifugalization. Mean differences between centrifugal and dilution results varied with the method from  $2.0 \pm 1.2$  to  $17.9 \pm 10.8$  per cent of the packed cell volume. Most dilution procedures are not well adapted to accurate serum volume estimates. The authors conclude that correction of conventional hematocrit results by a constant factor based on dilution methods is not justified.

R.C.C.

## BLOOD GROUPS

MOTHER-CHILD ABO INCOMPATIBILITY. A RELATION OF SECRETOR STATUS TO MENTAL DEFICIENCY. *H Yarnit and R Lieberman* From the Southbury Training School and the Department of Pediatrics Yale Medical School, Southbury Conn. *Am J Dis Child* 76 176-183 1948

Theoretically fetal damage from ABO maternal isoimmunization may result when the concentration of A or B factor in the child's body fluids is not sufficiently great to neutralize A or B maternal agglutinins.

Two hundred and eighty mentally deficient children were studied to determine the incidence of mother-child ABO incompatibility and the secretor status of the child. One hundred and fifty-seven of these had clinically defined mental deficiencies such as mongolism and were used as controls whereas the remaining 123 were classified as undifferentiated congenital amentia of unknown origin. Evidence is presented to show the unreliability of the study of a single undiluted specimen of saliva or gastric juice and in this study secretor status was determined only after both gastric juice and saliva were simultaneously examined and titrated.

There were 20 children who showed ABO maternal incompatibility and a nonsecretor status. The incidence of incompatible nonsecretors was greater in the group of undifferentiated mental deficiency (13 per cent) than in the control group (3 per cent) and it is suggested that ABO isoimmunization may be an etiologic factor in a small proportion of children classified as undifferentiated congenital deficiencies.

Even if confirmatory evidence were forthcoming it would be necessary to conclude, from the significant clinical differences pointed out by the authors, that the mechanisms responsible for cerebral damage in ABO and Rh incompatibility are not similar. One wonders because of the variable nature of secretor status whether the concentration of A or B factor in body fluids later in life is a valid measurement of that present in the prenatal and neonatal states.

H W B

IMMUNIZATION OF BLOOD DONORS WITH SALIVA V. Bzdorsky From the State Health Institute, Prague, Czechoslovakia. *Čas. lékař. Čes.* 87: 725, 1948.

Immunization of blood donors with diluted saliva of A and B secretors performed according to Wiener's proposal increased the titer of hemagglutinins in 80 per cent of cases; the hemagglutinin titer rose on an average eight times and was constant even after nine months. Better results of immunization were obtained in persons under the age of 45.

M N

SECTION 6. MICROBIOLOGY (a) THE RH FACTOR—GENERAL SIGNIFICANCE AND METHODS OF STUDY. P. Levine From the Ortho Research Foundation, Raritan, N. J. (b) RECENT VIEWS ON THE GENETICS OF THE RH BLOOD FACTORS. H. H. Strandskov From the University of Chicago, Chicago, Ill. (c) MEDICOLEGAL ASPECTS OF THE RH BLOOD TYPES. A. S. Wiener From the Office of the Chief Medical Examiner of New York City, New York, N. Y. (d) APPRAISAL OF THE CLINICAL ASPECTS OF THE RH FACTOR. P. Vogel From the Mount Sinai Hospital and Department of Health, New York City, New York, N. Y. *Bull. New York Acad. Med.* 25: 244-263, 1949.

These four papers deal briefly with the current views on the genetics of the Rh blood factors, the medical application of our knowledge of the several known blood types, the methods of detection of immunization by the Rh factor, and the management of erythroblastosis fetalis.

The author of the second paper proposes the use of the basic locus symbol Rh with the letters CDE as superscripts to clarify further the nomenclature introduced by Fisher and Race. The two gene hypotheses to account for inheritance of Rh blood types (e.g., the S allele hypothesis and the two-allele hypothesis) are discussed by the same author from the point of view of serologic evidence, gene results, and evidence obtained from gene-genotypic and phenotypic frequency analyses.

BLOOD TRANSFUSIONS AND THE RH FACTOR. P. G. Hattersley From the Department of Medicine, University School of Medicine, San Francisco, Calif. *California Med.* 37: 325-329, 1949.

Two cases are reported: one of fatal erythroblastosis in first and second pregnancies of a Rh-negative patient previously immunized by transfusions; the other of a major hemolytic reaction in a Rh-negative male patient previously immunized by a single transfusion of Rh-positive blood. The author further points up the necessity of administering Rh-negative blood only to Rh-negative patients. A second reaction was notable in that while laboratory evidence of complete hemolysis was absent within two hours of transfusion, was dramatic clinical symptom of a major hemolytic reaction.

# BOOK REVIEWS

*An Atlas of Bone Marrow Pathology* By M. C. G. ISRAEL'S New York Grune & Stratton 1948 \$6 50 79 pages

This small book of 79 pages centers around twelve color plates of marrow cells seven plates being composed of groups of single cells and five plates made up of various abnormal conditions. The descriptions of cell morphology are unusually good with the simplicity and lucidity we have come to associate with Israel's work. The black and white line drawings and the color plates are accurately done, although the latter lack brilliance. The Atlas can be recommended as a primer in the study of marrow puncture techniques.

*Hematology* By CYRUS C. STURGIS Springfield Ill C. C. Thomas Company 1949 \$12 50

*Hematology* ed. 2. By WILLIS M. FOWLER New York P. B. Hoeber Inc. 1949 \$8 50

Recent American texts of hematology are rapidly filling the large gap formerly existing in this country between the wide interest in the subject and the available number of standard works. Sturgis' large tome is new. Fowler's which is slanted frankly for students and practitioners is presented as a revised second edition.

Sturgis has an interesting preface in which he presents some of his views about hematology as a specialty the importance of some knowledge of the historical aspects of a given subject and of a carefully edited and comprehensive bibliography. The book begins in a rather unorthodox way in that the anemias are dealt with first. There is no attempt to delve into such matters as blood formation histology of blood cells etc. that are customarily discussed in the first few chapters of a hematologic text. Perhaps this is justified for a book of this type since many practitioners would probably skip such sections and if they were sufficiently interested could consult some more complete reference work on the subject. The book, from this viewpoint is eminently practical. The comprehensive historical discussions are of unusual interest and not to be found in any other similar work. They are worth the price of the book alone. The bibliographic references 1830 in number are presented numerically at the bottom of the pages referring to the publications in question and are repeated in more than fifty pages of alphabetically arranged bibliography at the end of the book.

There can be no question but that Sturgis' work is a valuable addition to the hematologic literature although some might criticize the methodology of presentation and the lack of both cytologic and physiologic approach to the various diseases.

Fowler's revised book is a distinct improvement over the first edition. It is more carefully written. It reflects adequately the advances made in the past few years and should serve as a primer in hematology.

### DIAGNOSIS AND MECHANISM OF HEMOLYSIS IN CHRONIC HEMOLYTIC ANEMIA WITH NOCTURNAL HEMOGLOBINURIA

By J V DACIE, M B , M R C P , LONDON

CHRONIC hemolytic anemia with nocturnal hemoglobinuria or nocturnal hemoglobinuria is an uncommon but most interesting form of chronic hemolytic anemia. Despite major contributions to the understanding of the mechanism of hemolysis made by Ham<sup>1, 2</sup> and Ham and Dingle<sup>3</sup> in 1937 and 1939, and by Dacie, Israëls and Wilkinson<sup>4</sup> and Jordan,<sup>5</sup> working independently at about the same time, the essential basis of the disease is still a mystery. The above mentioned workers showed that the primary abnormality resided in the patient's own erythrocytes, a proportion of which would undergo hemolysis when suspended in vitro in fresh unheated serum obtained either from the patient or from normal subjects. To demonstrate a significant amount of hemolysis of the patient's corpuscles, it was, however, found to be necessary to add acid or carbon dioxide to the serum to compensate for the alkalinity which followed loss of carbon dioxide when the serum was exposed to air. Without addition of acid there was little or no hemolysis. The factor in serum causing hemolysis was found to be thermolabile, for heating to 56°C quickly abolished its hemolytic activity, and characteristically, the hemolytic activity of heat-inactivated serum could not be re-established by the addition of fresh guinea pig serum. In contrast to the behavior of the patient's erythrocytes, normal corpuscles were *not* hemolysed by the patient's serum.

These observations on hemolysis in vitro have been confirmed in vivo, transfusion experiments employing the Ashby method of differential agglutination<sup>6</sup> have demonstrated that normal erythrocytes survive for a normal length of time after transfusion into patients suffering from nocturnal hemoglobinuria.<sup>7, 8</sup> Moreover, transfused normal erythrocytes separated by differential agglutination from those of the recipient after ten days in the recipient's circulation did not undergo hemolysis in vitro when resuspended in acidified serum.<sup>9</sup> On the other hand, it has been recently shown that when patient's corpuscles are transfused to a normal recipient, a proportion is rapidly destroyed.<sup>10</sup> The results of these transfusion experiments are thus essentially similar to those which have been obtained in congenital hemolytic anemia<sup>6</sup> and in sickle cell anemia,<sup>11</sup> disorders in which tests in vitro also indicate that the erythrocytes themselves are abnormal. It was clearly a failure to appreciate the importance of pH that had led the

From the Department of Pathology Postgraduate Medical School of London, London E 8 1 2 3

majority of earlier workers to report that tests for hemolysis *in vitro* were negative in this disease. Van den Bergh,<sup>1\*</sup> however, as far back as 1911, using carbon dioxide as acidifying agent, obtained positive results, and in part he anticipated later observations.

At the present time this unusual corpuscular sensitivity to hemolysis in acidified serum is widely utilized in the diagnosis of nocturnal hemoglobinuria, and has often been referred to as Ham's test. The mechanism behind the effect is, however, still obscure, and its essentially nonspecific nature not generally appreciated. In this paper some further details are presented concerning the effect of pH on hemolysis *in vitro* in nocturnal hemoglobinuria, and this is followed by a consideration of the specificity of the acidified (acid) serum test and its use in diagnosis. Finally, the nature of the hemolytic mechanism in nocturnal hemoglobinuria is discussed. Three patients have been available for study. Earlier observations made upon them have been previously reported.<sup>7, 10, 13, 14</sup>

### HEMOLYSIS *IN VITRO* IN NOCTURNAL HEMOGLOBINURIA

As has already been shown in an earlier publication,<sup>12</sup> the acid-serum test depends upon the adjustment of the pH of the serum to an optimum by the addition of acid. If differing amounts of either hydrochloric, sulphuric or lactic acids are added to equal volumes of serum before the addition of the suspension of corpuscles, a pH-hemolysis curve may be obtained.<sup>13\*</sup> It will then be seen that hemolysis of patient's erythrocytes in serum is maximal at pH 7.0 to 7.4, that is at the physiologic level or a little below, and is inhibited above pH 8 and below pH 6.† As has already been mentioned, serum allowed to stand exposed to the air loses carbon dioxide, with the result that its pH ultimately rises to about 8. This slight alkalinity explains the negative tests for hemolysis which result if the effect of pH is neglected and acidification omitted.

However, hemolysis in unacidified human serum may be observed if a small amount of fresh guinea pig serum is added to it. If the pH range for hemolysis is ascertained after the addition of guinea pig serum, the curve will be found to be skewed, not only is the total amount of hemolysis increased within the range pH 6-8, but hemolysis takes place well to the alkaline side of pH 8 (fig. 1). This is because under these conditions hemolysis in part results from the presence of anti-human heterolysin in the guinea pig serum, to which the patient's corpuscles are unusually sensitive.‡ (see later). Skewness of the pH-hemolysis curve is abolished and hemolysis merely increased within the pH range 6-8, if the anti-human antibodies are removed from the guinea pig serum by previous absorption with normal erythrocytes. This increase in hemolysis is probably due to an increase in serum complement.

\* pH hemolysis curves very similar to those recorded by Dacie and Richardson<sup>13</sup> have by now been obtained using the erythrocytes from 5 patients in all.

† These pH values refer to readings made after the addition of the suspension of corpuscles and after 1 hour's incubation at 37°C.

‡ The use of guinea pig serum in the diagnosis of nocturnal hemoglobinuria is however *not* recommended. The titer of the heterolysin is an unknown factor and normal corpuscles may be hemolyzed to some extent also.

The wide pH-hemolysis range for the hemolysis of patient's corpuscles by human serum and fresh unadsorbed guinea pig serum containing anti-human heterolysin corresponds to the pH range for the action of guinea pig complement,<sup>15</sup> and is similar to the pH range for the hemolysis of human erythrocytes by human complement and isohemolysin<sup>16</sup>, in each case, hemolysis takes place well to the alkaline side of pH 8 and is readily observed without it being necessary to acidify the serum.

### *The Acid-Serum Diagnostic Test*

As already indicated, the acid-serum test depends upon the adjustment of pH to an optimum level for the action of the serum factor (the nature of which is dis-

FIG. 1. pH hemolysis curves (A) for the hemolysis of patient's cells in fresh human serum. Curve B represents the curve obtained with the addition of fresh guinea pig serum; the extension to the left is due to the presence of anti-human heterolysin. Curve C shows the effect of addition of guinea pig serum from which all heterolysin had been absorbed; there is an increase in hemolysis but the curve is of the same shape as with human serum alone. The black arrows indicate the amount of hemolysis obtained when serum was used to which no acid or alkali had been added. Fresh guinea pig serum at a final concentration of 1:12 was used in the above experiment. Anti-human heterolysin was absorbed from it by adding to it an equal volume of washed packed human erythrocytes and allowing the mixture to stand for two hours at 4°C before centrifuging. pH was measured with a glass electrode after the suspension had been incubated at 37°C for one hour and hemolysis measured approximately against standards.

cussed in a later section of this paper). For this purpose, Ham<sup>7</sup> recommended the addition to serum of 5 per cent by volume of 0.85 normal lactic acid or N, HCl. However, the amount of acid required for maximal hemolysis needs to be judged carefully, for its effect will vary with the buffering power of the serum proteins and with the method of obtaining serum, and also with the strength of the suspension of corpuscles subsequently added. If serum is obtained by defibrinating blood in an open flask, a procedure which results in the rapid oxygenation of the blood, loss of carbon dioxide and a rise in pH to about 8.0, 10 per cent by volume of N, HCl is then generally the right amount of acid to add for maximal hemolysis. If 10 per cent by volume of a 50 per cent suspension of washed patient's corpuscles is finally added. It should be stressed that in nocturnal hemoglobinuria hemolysis in acidified serum is not the result of increased corpuscular sensitivity to the acid.

of acid per se. That this is so can be shown by suspending patient's corpuscles in serum previously heated to 56 C for 10-30 minutes, under these circumstances, hemolysis within the pH range 6-8 will not take place, and the corpuscles are not clearly distinguishable from normal erythrocytes (fig. 2).

Nevertheless, increased corpuscular sensitivity to acid may be encountered, and this may lead to errors in diagnosis unless this possibility is appreciated. In con-

genital or acquired hemolytic anemia, the erythrocytes, if sufficiently spherocytic, will undergo hemolysis in normal serum at a pH (6-7) at which normal corpuscles do not hemolyze. In this way, the acid-serum test may appear to be positive. Under these circumstances, however, contrary to the findings in nocturnal hemoglobinuria, hemolysis will not be prevented if the serum is inactivated by heating.

The two experiments described briefly below illustrate the increased sensitivity of spherocytes to hemolysis in acidified sera.

1. The blood was derived from a patient R. L. suffering from idiopathic acquired hemolytic anemia. Anemia was severe, hemoglobin 4.6 Gm., erythrocytes 1,200,000 per cu. mm. with 50 per cent reticulocytes. There was marked spherocytosis and a considerable increase in osmotic fragility. Hemolysis com-

mened at 0.75 per cent NaCl, with 50 per cent hemolysis at 0.54 per cent NaCl and complete hemolysis at 0.30 per cent NaCl. The Coombs test was strongly positive.

Defibrinated patient's blood was centrifuged and the deposited erythrocytes well washed in isotonic saline and finally resuspended as a 5 per cent suspension. Part of the patient's serum was heated to 56°C.

FIG. 2. pH hemolysis curves using human serum heated to 56°C for thirty minutes. The curves for normal corpuscles (1) and for corpuscles from nocturnal hemoglobinuria (2) are not hemolyzed at a pH above 6. The curves for corpuscles from cases of (3) acquired hemolytic anemia and (4) congenital hemolytic anemia are hemolyzed at a higher pH and would give a positive acid serum test. The curves were obtained by adding 10 per cent by volume of hydrochloric acid ranging in strength from 1/20 to 1/2.5 to the serum. The corpuscles were added 0.05 to give a final suspension of 5 per cent.

thirty minutes the remainder was kept frozen in the refrigerator until use. Five ml. of each of the fresh serum and of the heated serum were delivered into two series of small tubes. Serum 0.05 ml. and 0.05 ml. volumes of a range of strengths of hydrochloric acid added to each tube. The tubes had been well mixed into the serum 0.05 ml. volumes of the corpuscles were added to each tube.

10 each tube. The tubes were gently centrifuged after the addition of the suspension of corpuscles had been completed (i.e. after approximately ten minutes at room temperature) and hemolysis estimated by visual comparison with standards made from hemolyzed patient's blood. The deposited corpuscles were then resuspended and the two series of tubes incubated for two hours at 37° C. The tubes were then re-centrifuged and hemolysis estimated as before.

The above procedure was repeated using freshly withdrawn compatible normal serum instead of the patient's serum. The results are given in table 1.

2. The above experiment was repeated using washed corpuscles from a normal subject and from patients with nocturnal hemoglobinuria and congenital hemolytic anemia. This last patient was a young woman aged 27 with moderate anemia, hemoglobin 9.8 Gm. and erythrocytes 3,300,000 per cu. mm. with 13 per cent reticulocytes. There was a considerable increase in osmotic fragility; hemolysis commenced at 0.72 per cent NaCl with 50 per cent hemolysis at 0.47 per cent NaCl and complete hemolysis at 0.30 per cent NaCl. The Coombs test was negative.

Normal serum inactivated by heating to 56° C. for thirty minutes was used and acidified before the addition of the corpuscle suspensions as described for the previous experiment. The tubes were centrifuged after incubation for thirty minutes at 37° C. Hemolysis was estimated by diluting volumes of the supernatants 10 N/10 NaOH and estimating the liberated hemoglobin as alkaline hematin. The pH of the tubes in which there was no hemolysis was measured approximately after incubation and centrifugation by means of the indicators brom thymol blue and methyl red. The results of this experiment are given in table 2 and in figure 2.

The onset of hemolysis appears to be due to the increased sensitivity of spherocytic corpuscles to hemolysis produced by a fall in pH, as well as to the slight alterations in tonicity resulting from the addition of 10 per cent by volume of dilute acid to the serum. Bittorf,<sup>17</sup> in 1914, reported that the resistance to acid of erythrocytes from patients with congenital hemolytic anemia was decreased, but gave no details of his experiments, and little attention seems to have been paid to this phenomenon. The effect of pH on the swelling of erythrocytes in isotonic and hypotonic media has been admirably demonstrated by Hampson and Maizels<sup>8</sup>, in phosphate buffers, increasing acidity causes increasing swelling which reaches a maximum at pH 5.4. Swelling similarly takes place if corpuscles are suspended in serum or plasma of increasing acidity, and it seems likely, therefore, that a major factor in determining the increased liability of spherocytes to hemolyze in acid as well as in hypotonic media is their reduced ability to swell to the same extent as do normal corpuscles.

Of more importance, perhaps, than the appreciation that spherocytes hemolyze unusually easily in acidified sera, is the observation that enhancement of serum hemolytic activity by the adjustment of pH to an optimum by the addition of acid seems not confined to the hemolytic reaction in nocturnal hemoglobinuria. In this laboratory, this effect has been observed in two other quite distinct types of immune hemolytic systems. In each case, as in nocturnal hemoglobinuria while little or no hemolysis occurred in unacidified serum, hemolysis was strikingly obvious if 10 per cent by volume of N/5-N/3 HCl was added to the serum before the addition of the suspension of corpuscles. Thus, a positive acid serum test has been observed in—

(a) *Acute hemolytic (hemolytic) anemia*. In a patient suffering from severe hemolytic anemia, who is the subject of a separate report,<sup>16</sup> an abnormal warm hemolysin was present in the serum, and the patient's corpuscles having absorbed

of guinea pig serum to reactivate inactivated human serum and the sensitivity of patient's erythrocytes to heterohemolysins and isohemolysins (see later) are confirmatory, but need not necessarily be carried out

### *Sensitivity of Patient's Erythrocytes to Other Hemolytic Systems*

There is no characteristic morphologic abnormality of the erythrocytes of patients with nocturnal hemoglobinuria. There may be a considerable degree of macrocytosis, as is often seen in anemia associated with rapid erythrocyte regeneration, but there is no spherocytosis, and osmotic fragility and mechanical fragility are normal. Ham and Dingle<sup>3</sup> have reported normal resistances to saponin and sodium taurocholate, and Shapiro<sup>19</sup> a normal resistance to lysocephalin. Ham and Dingle also made an important observation when they showed that the erythrocytes from a patient with nocturnal hemoglobinuria were more sensitive than normal corpuscles to hemolysis by an anti-human antibody prepared by

TABLE 3—*Diagnosis of Nocturnal Hemoglobinuria: Acidified Serum Test and Necessary Control Observations*

immunizing a rabbit with washed human erythrocytes. The patient's erythrocytes were also hemolyzed by human isohemolysin more readily than were normal corpuscles.

These phenomena have been reinvestigated and these increases in sensitivity found to be most striking. Complement is required for hemolysis by isohemolysin but either fresh guinea pig or human serum can be used, and no adjustment of pH is necessary. In the case of one patient of blood group A Rh positive, it was found that the patient's erythrocytes were more sensitive only in respect of hemolysis, when suspended in a range of dilutions of an anti-A serum they were agglutinated to about the same serum dilution as were normal corpuscles. However, when complement was added, in striking contrast to the behavior of the normal corpuscles the patient's erythrocytes were hemolyzed to about the same serum dilution as they were agglutinated. In fact, a proportion of the patient's erythrocytes were

diagnostic test for nocturnal hemoglobinuria. Positive results (obvious hemolysis within six hours of incubation at 37 C) have been observed in acquired hemolytic anemia with marked spherocytosis as well as in nocturnal hemoglobinuria and in hemoglobinuria associated with high titer cold antibodies unless strictest precautions against chilling were taken.

hemolyzed by all of thirteen naturally occurring anti-A sera,\* of agglutinating titers (final dilutions of serum) ranging from 1/8 to 1/1024. That some corpuscles were hemolyzed by a serum with the low agglutinin titer of 1/8 is especially interesting and suggests that even low titer sera have unexpected hemolytic properties. The use of erythrocytes from patients with nocturnal hemoglobinuria

TABLE 4.—*Comparative Sensitivity to Agglutination and Hemolysis by anti A anti D and anti M of Normal Erythrocytes and the Corpuscles from a Patient with Nocturnal Hemoglobinuria*

The patient's corpuscles were agglutinated to approximately the same titer as were the normal erythrocytes, but were much more sensitive to hemolysis. The titers recorded as end points were final dilutions of serum. The corpuscles were washed in saline and used at a final concentration of 1 per cent. Fresh serum from a Group A subject was used at a final dilution of 1/6 as a source of complement. The tubes were kept at 37°C for thirty minutes after the corpuscles had been allowed to sediment at room temperature, end points of hemolysis were read by visual inspection. End points of agglutination were read microscopically after two hours at room temperature in a duplicate series of serum dilutions to which no complement was added. The incomplete anti D serum was titrated in 20 per cent albumin.

Type of serum	Agglutinin titer Patient's corpuscles (Group A)	Hemolysin titer

would thus appear to make more delicate any tests designed to demonstrate the hemolytic properties of anti-A (or anti-B) sera. With Rh antibodies, however, no differences between patient's and normal corpuscles have been demonstrated. The patient's erythrocytes were not hemolyzed by any of four in saline agglutinating antibodies of titer 1/128 to 1/3000 or by an incomplete antibody of titer 1/1000.

I am indebted to Dr. L. Shapiro for technical help with some of these titrations.

in albumin. Similarly, no hemolysis was caused by two anti-M sera of moderate agglutinating titer (table 4).

#### THE SERUM FACTOR REQUIRED FOR HEMOLYSIS AND THE NATURE OF THE HEMOLYTIC MECHANISM

It is not yet clear whether or not the serum factor required for hemolysis is identical with the serum complex known as complement. Evidence suggesting that complement is involved is provided by the fact that guinea pig serum will increase the amount of hemolysis produced by human serum and will, as shown by Ham and Dingle,<sup>3</sup> restore activity to zymine or ammonium hydroxide treated human serum. Moreover, there appears to be a general relationship between a serum's ability to hemolyze patient's erythrocytes at optimum pH and its complement content, as estimated against sheep corpuscles sensitized with rabbit anti-sheep hemolysin, at least in the case of adult human sera. In six experiments utilizing eighteen sera, statistical analysis of the data recorded in table 5 indicates that the two activities probably increase or decrease in parallel ( $p < 0.01$ ). This does not, however, prove that the factors concerned are identical and it might be added that Ham and Dingle<sup>3</sup> could not demonstrate any fixation of complement by patient's erythrocytes in excess of that absorbed by normal corpuscles when acidified serum was subjected to successive absorptions with patient's and normal corpuscles respectively. Unquestionably, however, a specifically human factor is required, for guinea pig serum alone will not cause hemolysis. There is also other evidence which suggests that some factor other than human complement is required, for instance, Ham and Dingle showed that lyophilisation of serum reduced its hemolytic activity without demonstrably altering complement activity against sensitized sheep corpuscles, and that heating to from 45°C to 50°C, filtration through Berkfeld candles and storage at room temperature removed hemolytic activity more readily than complementary activity. Moreover, as has been already referred to, there are marked differences between the pH requirements for hemolysis of patient's erythrocytes in normal serum and the hemolysis by human or guinea pig complement of corpuscles sensitized by isohemolysin or heterohemolysin.<sup>18</sup>

There is thus some evidence for and some evidence against the participation of human serum complement in the hemolysis by serum of the erythrocytes of patients with nocturnal hemoglobinuria, and in the present state of knowledge any theory for the mechanism of hemolysis can only be speculative. It is suggested as a tentative hypothesis that the increased hemolysis *in vivo* is dependent upon a corpuscular abnormality whose effect is to increase the sensitivity of the erythrocytes to certain hemolysins of immune body type. All grades of increased sensitivity are encountered: some cells are extremely easily hemolyzed, others hemolyze less readily and some perhaps behave normally. Presumably, the surface structure of the corpuscles which hemolyze unusually easily is more receptive (there are more receptors) for the hemolysin component of anti-erythrocytic antibodies than in normal corpuscles, which seem to be distinctly insensitive to hemolysis although sensitive to agglutination. This type of abnormality could explain the ease with which patient's erythrocytes are hemolyzed by iso-antibody and hetero-antibody.

Unduly rapid hemolysis *in vivo* could also be explained on these lines if the existence is postulated in all sera of a potentially hemolytic substance of low activity which perhaps fails to affect normal corpuscles seriously, but to which the patient's erythrocytes are fatally sensitive to a greater or less degree because of their hypothetical surface abnormalities. It is admitted that this normally occur-

TABLE 5—*Comparison in Six Experiments of the Hemolytic Activity of Eighteen Fresh Adult Human Sera against Suspensions of Sheep Corpuscles Sensitized with 5 m h d Rabbit anti Sheep Corpuscle Serum and against Nocturnal Hemoglobinuria Erythrocytes*

The serum was used at a final concentration of 1:30 for estimation of its ability to hemolyze the sensitized sheep corpuscles and undiluted and acidified to optimum pH when used with the nocturnal hemoglobinuria erythrocytes. The tubes were incubated in pairs or groups of four for 5 minutes at 37°C and then chilled and centrifuged. The amount of hemolysis in the supernatants was estimated photoelectrically.

The data obtained has been analyzed by the theory of probability. This shows that the correspondence in ranking order of the data in the two columns is most unlikely to have been determined by chance alone ( $p < 0.01$ ).

ing hemolytic substance in serum is only hypothetical and that there is no real evidence of its existence as a separate entity. Nevertheless, for reasons already advanced, it seems almost certain that something different from or in addition to the usual fractions of complement is involved in the hemolysis of patient's corpuscles. If, however, the pH requirements for the absorption of this hemolytic substance are similar to those recently observed<sup>10</sup> as characterizing the par-

hemolysin present in the serum of a patient with acute hemolytic anemia, the effect of pH on hemolysis in vitro would be that which is, in fact, observed in nocturnal hemoglobinuria

### SUMMARY

1 Studies in vitro and transfusion experiments indicate that the cause of nocturnal hemoglobinuria is an abnormality of the erythrocytes. In vitro, patient's corpuscles undergo hemolysis in fresh human sera, but only within a pH range of 6 to 8, a range more restricted on the alkaline side than the limits within which isohemolysis will take place.

2 The nonspecific nature of the acid-serum test is emphasized. In addition to nocturnal hemoglobinuria, positive tests for hemolysis may be obtained in this way with certain warm and cold hemolysins, and in the presence of marked spherocytosis. The control observations necessary for the diagnosis of nocturnal hemoglobinuria are described.

3 The erythrocytes in nocturnal hemoglobinuria are remarkably sensitive to hemolysis by anti-A (or anti-B) but are not hemolyzed by anti-Rh.

4 It is suggested as a hypothesis that the same abnormality, presumably at the corpuscular surface, which is the cause of the increased sensitivity to hemolysis by anti-A results in the erythrocytes being fatally sensitive in vivo to a hemolytic factor distinct from complement and normally present in serum.

## ACQUIRED HEMOLYTIC ANEMIA

### I THE RELATION OF ERYTHROCYTE ANTIBODY PRODUCTION TO ACTIVITY OF THE DISEASE II THE SIGNIFICANCE OF THROMBOCYTOPENIA AND LEUKOPENIA

By ROBERT S EVANS, M D , and ROSE T DUANE, A B

IT IS NOW evident that the syndrome of acquired hemolytic anemia represents a distinct entity which is separate in pathogenesis and course from the commonly described familial hemolytic jaundice. This distinction, which was recognized by the writers of the early part of the century, was lost sight of by many more recent observers, who suggested that acquired hemolytic anemia was simply a sudden outcropping of a latent inborn defect. Since spherocytosis of the red cells is always present in congenital hemolytic jaundice and is sometimes observed in acquired hemolytic anemia, the confusion was natural, particularly when a sharp distinction could not always be made on clinical grounds. Beginning with the red cell survival experiments of Dacie and Mollison,<sup>1</sup> it has become increasingly evident that acquired hemolytic anemia is caused by a hemolysin \* active for all erythrocytes, while congenital hemolytic jaundice is due to a defect in red cell structure.<sup>2</sup> During the last few years it has been possible to demonstrate sensitization of erythrocytes from patients with acquired hemolytic anemia with immunologic technics developed in the field of Rh sensitization.<sup>3, 7</sup> We have some evidence, then, by analogy, that the hemolytic agent in acquired hemolytic anemia is an immune body similar to the univalent or hyperimmune Rh antibody and may be a response to antigenic stimulus. The ready demonstration of the abnormal immune mechanism in acquired hemolytic anemia elevates this rather rare disease from the position of an obscure hematologic phenomenon of uncertain etiology to the general field of abnormal immunology. Because of the unique properties of erythrocytes, the affected tissue can be isolated and subjected to close observations so that variations in the rate of production of the hemolysin can be measured in relation to severity of the disease and to any type of therapeutic procedure.

It is worthwhile at this point to summarize our knowledge of the antibody like agent which appears to be responsible for the destruction of red cells in acquired hemolytic anemia.

1. The destructive agent appears to be a fraction of plasma protein, probably a globulin, since erythrocytes from persons with acquired hemolytic anemia are agglutinated with the anti-human serum rabbit serum of Coombs, Mourant and Race,<sup>3</sup> as are cells sensitized by Rh hyperimmune antibody. Red cells from normal individuals and from patients with other types of disease are not agglutinated by this reagent.

From the Department of Medicine Stanford University School of Medicine San Francisco Calif

\* The word hemolysin is used as an all inclusive term for agents known to bring about destruction of red blood cells

2 The hemolytic agent is also similar to the univalent or hyperimmune Rh antibody in that sensitized cells do not usually agglutinate in saline but require a more complex colloidal medium. Whole serum, 30 per cent beef albumin and 2 per cent acacia in 1.5 per cent calcium chloride have been found to provide the necessary factors to allow agglutination to take place.

3 Since accelerated hemolysis proceeds at a fairly constant rate in acquired hemolytic anemia, it appears that the agent does not require special conditions of temperature or pH for activity as is the case in some hemolytic syndromes. In keeping with this property of constant activity of the hemolysin it has been our experience that the immune body could be found on the surface of the cell when it could not be demonstrated in the serum.

4 We have been able to remove the sensitizing agent from the surface of the red cell by heating a suspension of the sensitized cells to 56°C. in normal saline.<sup>5</sup> The immune body appeared to remain active to some degree in the saline eluate since normal cells exposed to it became agglutinable in the Coombs reagent. This observation is considered further evidence that the hemolytic agent is an immune body. So far this observation that the lytic agent can be transferred to normal cells has not been confirmed by others, and we have been successful in further attempts in only one of three patients.

5 The agent is active for all erythrocytes since transfused cells appear to be destroyed at a rate which approximates the rate of destruction of the native cells.

Although the etiologic significance of the antibody-like abnormality found in acquired hemolytic anemia appears to be established, the study of patients who appeared to have recovered completely following splenectomy showed a persistence of the abnormality. The erythrocytes from patients in remission were found to be agglutinable in the anti-human globulin serum even though all evidence of accelerated hemolysis had subsided. This observation appeared to throw some doubt on the significance of sensitization as a primary cause of the disease. It seemed possible that the agglutinability of the erythrocytes in the various media could be the result rather than the cause of the disease, and that splenectomy produced a remission by removal of the principal site of destruction of abnormal cells. On the other hand, it appeared more likely that a quantitative relationship between the amount of immune body present and the rate of blood destruction might explain the apparent paradox. We attempted, therefore, to devise a method of quantitating the amount of antibody on the red cell so that measurements could be made during active and quiescent phases of the disease. In this report we are presenting evidence of a direct relationship between the amount of antibody on the cell and the activity of the hemolytic process.

Ten rabbits were injected subcutaneously at weekly intervals with 0.5 cc. of fresh human serum for six weeks. Following an interval of one month a second course of injections was given before the animals were sacrificed and the sera collected. The red cell agglutinins in the rabbit serum were adsorbed by mixing the sera in 5 cc. amounts with equal quantities of a 50 per cent suspension in normal saline of pooled Group A, B and O cells that had been washed repeatedly to remove serum protein. The mixture was then incubated at 37 C. for one hour with frequent agitation before centrifugation and removal of the supernatant fluid. Two such adsorption procedures sufficed to remove all of the cell agglutinins. It was found important to use O cells as well as those of Group A and B, since agglutinins specific for O cells appeared in low titer if O cells were not included in the adsorption process.

Once the rabbit serum was completely adsorbed, it did not agglutinate washed human cells of any group or type in any concentration. It was then filtered, placed in small vials and kept in the frozen state where it maintained its original activity.

The amount of antibody for human serum protein in the adsorbed rabbit serum may be determined by precipitation titers. However, the authors found that the most practical method of assaying the rabbit serum was to determine the highest dilution at which cells sensitized in a uniform manner with Rh<sub>0</sub>

blocking antibody were agglutinated. This was done by exposing Rh<sub>1</sub> cells of one individual to a high concentration of Rh<sub>0</sub> blocking antibodies for one half hour at 37 C. The Rh<sub>0</sub> blocking serum used showed an agglutinin titer of 1-5000 in beef albumin and was used in a dilution of 1-20 to sensitize the Rh<sub>1</sub> cells. The sensitized cells were washed three times in normal saline and added to the saline dilutions of the rabbit serum and incubated for one half hour at 37 degrees before brief centrifugation and microscopic observation of the end point of agglutination. The two sera used have shown a consistent ability to agglutinate Rh<sub>1</sub> cells so sensitized in dilutions of 1-320 plus or minus one dilution.

Red cells from patients with acquired hemolytic anemia tested for sensitization were collected from venous or capillary blood and diluted directly in normal saline. The cells were washed three times with normal saline and a final 2 per cent suspension was approximated. A drop of the suspension was then added to a drop of rabbit serum and left for one half hour at room temperature and subjected to brief centrifugation before observation of agglutination. Cells from patients with active acquired hemolytic anemia showed a nearly complete agglutination in a 1 to 10 dilution of the anti globulin rabbit serum indicating that most if not all the cells were sensitized. Suitable control suspensions showed no agglutination. It was noted that cells from patients with acquired hemolytic anemia were agglutinated by varying dilutions of the rabbit serum, so observations were made to determine if the amount of antibody on the cell surface had an inverse relationship to the concentration of rabbit serum required to produce agglutination. That such an inverse relationship exists is shown by the analogy with cells sensitized by varying concentrations of Rh<sub>0</sub> blocking antibody. Rh<sub>1</sub> cells were incubated one hour at 37 C. in serial dilutions of an anti Rh<sub>0</sub> blocking serum, washed and exposed to dilutions of antiglobulin serum and the end point of agglutination observed microscopically. The results are shown in table 1.

It is evident from the above that cells exposed to decreasing amounts of sensitizing antibody, below a concentration which saturates (1-20 to 1-320) require increasingly high concentrations of antiglobulin serum to produce agglutination. From this it may be inferred that avidity of patient's cells to agglutinate in the dilutions of the rabbit sera is proportional to the amount of antibody on the cell surface.

In the observations reported here we have used two preparations of antihuman globulin serum. Both show comparable activity for agglutination of Rh<sub>0</sub> cells that have been sensitized by blocking antibody. However, we have observed certain variations in the ability of these sera to agglutinate cells from patients with active disease. The cells of some patients show a consistently greater susceptibility to agglutination in one serum than the other. These observations indicate the importance of using several rabbit sera simultaneously to detect sensitization of erythrocytes in acquired hemolytic anemia.

#### DESCRIPTION OF PATIENTS

Eleven patients with acquired hemolytic anemia are included in this series. One of the patients has been described in detail in a previous report.<sup>8</sup> The diagnosis of hemolytic anemia in each patient was based on the presence of a chronic anemia,

reticulocytosis, an increase in serum bilirubin and, in most patients, the demonstration of an increased fecal urobilinogen. All patients showed erythroid hyperplasia of the bone marrow. The patients in the series were grouped together under the heading of acquired hemolytic anemia because of an absence of a family history of anemia or jaundice and a lack of any personal history suggestive of hemolytic anemia prior to the onset of the present illness in adult life. In most instances, patients did not exhibit well-marked spherocytosis and increased osmotic fragility.

E. S., M., 78	Chronic lymphatic leukemia	26	7.8	- 3	20	30	

In further distinction to congenital hemolytic jaundice, the rapid destruction of normal transfused cells was evident when measured in seven of the patients. Other varieties of hemolytic anemia were excluded by appropriate tests.

In 5 of the 11 patients there was nothing to suggest a precipitating cause for the onset of hemolysis. In 6 of the patients there were a variety of conditions associated with onset of the disease which have been recorded in table 2, along with a summary of the basic data during the first few days of observation. The data

varied in severity from the mild to the very acute form, and in all patients the course was prolonged over a period of weeks, months and even years, so there was ample opportunity to make serial observations to confirm the initial data recorded in the table

## RESULTS

### *1 Activity of the Hemolytic Process in Relation to the Amount of Antibody on the Cell Surface as Measured by Agglutinability of the Erythrocytes in the Anti-globulin Serum*

For this purpose the patients may be divided into three groups as follows

1 Four patients were studied with the Coombs reagent in both the active phase and during a remission. In 2 of the cases (Nos. 1 and 7) the remission followed a splenectomy, and in the other 2 (Nos. 3 and 8) the remission occurred spontaneously after weeks of observation of the active state.

2 Two patients with persistently active disease did not have splenectomy. One of these (No. 2) died without benefit of splenectomy after several weeks of observation. The second patient is an elderly man (No. 11) who has hemolytic anemia in association with chronic lymphatic leukemia. Results of x-ray therapy will be discussed below.

3 Five patients have been studied with the antiglobulin serum technic following splenectomy. Two of these patients (Nos. 4 and 5) have active disease with anemia and rapid blood destruction, although there was evidence of some improvement following splenectomy. Three patients (Nos. 6, 9 and 10) were studied at periods of one year to eighteen months after continued remissions induced by splenectomy. In all examinations the erythrocytes showed agglutination in the antiglobulin serum.

In general, good correlation was found between activity of the disease and the amount of antibody on the surface of the red cell as measured by the technic described above. As shown in table 3, erythrocytes of patients with active disease were agglutinated by dilutions of antiglobulin serum which ranged from 1-80 to 1-1280. On the other hand, the erythrocytes of patients in whom the disease process had subsided so that the rate of hemolysis approached normal were agglutinated in ranges of 1 to 2 dilution up to 1-80.

There seemed to be some variation between individual patients as to the amount of antibody on the surface of the red cells in the active phase of the disease as compared to the amount present during a complete or partial remission. While most patients with active disease showed agglutination of cells by 1-160 to 1-320 dilution of the anti-globulin serum during the active phase of the disease, one patient (E. S., No. 11) had erythrocytes which were frequently agglutinated by dilutions of 1-1280 or 1-2500. On the other hand, the red cells of A. D., No. 8, who had a somewhat milder degree of anemia, were never agglutinated by dilutions greater than 1 to 80. However, when this patient entered a remission, which for a time appeared nearly complete, agglutination of erythrocytes was not present in dilutions greater than 1-5.

An exception to the generalization concerning agglutinability of the cells and

activity of the disease was observed in a patient (H. S., No. 5) in whom the disease seemed to be persistently active but whose erythrocytes on several occasions showed diminished susceptibility to agglutination as shown in table 4. There seemed to be no relationship between the severity of the anemia and the reticulocytosis to the amount of immune body on the surface of the red cell during the periods of observation. There are several possible explanations of this observa-

TABLE 3.—*Typical Hematologic Data in Relationship to Agglutinability of the Erythrocytes in Dilutions of the Anti globulin Serum*

Patient	State of Disease	Hematocrit	Reticulocytes	Icterus Index	Fecal Urobilinogen	Greatest dilution of anti globulin serum showing agglutination
1. C. S.	Active	21	8.0	30	2080	1-3-0
	Quiescent post splenectomy	41	1.2	5	125	1-20
2. C. A.	Active	28	22.0	100		1-64
3. W. G.	Active	26	18.0	20	450*	1-160
	Spontaneous remission	36	12.0	10		1-10
4. J. F.	Active disease after splenectomy	17	70.0	40		1-160
5. H. S.	Active disease after splenectomy	26	20.0	30	700	1-3-0
6. F. R.	Quiescent after splenectomy	40	1.0	10		1-40
7. O. W.	Active	23	12.0	10	1360	1-3-0
	Quiescent 3 months after splenectomy	33	1.6	8	20	1-1
8. A. D.	Active	34	13	20	1800	1-64
	Spontaneous remission	45	1%	10		1-5
9. D. B.	Quiescent 18 months post splenectomy	42	0.5			1-5
10. B. T.	Quiescent 12 months post splenectomy	42	4.0		3-6	1-5
11. E. S.	Active	28	--	30		1-6

The method is rough at best, and perhaps variations in technique of preparation of the cells accounted for loss of some immune body in those observations when the cells were not agglutinated by higher dilutions of the rabbit serum. Also, there may be fairly rapid variations in the amount of antibody present which are not reflected in the degree of anemia or reticulocytosis.

A second exception to the generalization that activity of the disease is related closely to the amount of antibody on the cell was observed in W. G. who entered a phase of spontaneous remission after six weeks of active disease with a well marked drop in agglutinability of the erythrocytes and then showed a return

the susceptibility of his cells to agglutination in higher dilutions (1-160) of the rabbit serum without immediate return of active anemia as shown in table 5

Of particular interest are the two patients (Nos 1 and 7) who were studied before and after splenectomy, since they provide data as to the mechanism of the response to splenectomy. In both patients there was a decrease in the agglutinability of the red cells in antiglobulin serum and a cessation of abnormal hemolysis during the week following splenectomy as shown in table 6

TABLE 4—Serial Observations on a Patient with Active Hemolytic Anemia whose Cells Occasionally Seemed to Show Diminished Amount of Antibody without Varying the Activity of the Distast

10-30	49	0.9	1-160

One of the patients (C S) showed a fall in the hematocrit and a rise in icterus index to 15 six weeks after splenectomy, accompanied by evidence of an increase in the amount of erythrocyte antibody on the cells, but no further evidence of relapse occurred. She was well and free of signs and symptoms of hemolytic disease six months later. The second patient (O W) had a relapse and died in a distant part of the state about three months after our last observations showed the process to be quiescent.

Serial observations have also been made of one patient (E S) during the course of x-ray therapy of chronic lymphatic leukemia. The essential data are shown in table 7.

TABLE 6—Data Showing the Effect of Splenectomy in Two Patients. There was rapid hematologic improvement and a drop in the concentration of antibody on the cell surface following splenectomy.

Patient	Hematocrit	Reticulocytes	Icterus index	Fecal Urobilinogen Mg./day	Greatest dilution of the anti-globulin serum producing agglutination
1. C. S., F. 44					
Before splenectomy	19	7.0	20	2080	1-320
1 wk. after splenectomy	43	1.0	5	210	1-1
6 wk. after splenectomy	35	1.6	15	125	1-160
6 mo. after splenectomy	41	1.1	5		1-20

9-8	30	8.2	8,500		1-320
9-15	30.5	10.0	7,500		1-160

It is of interest that there was an improvement in the anemia following a reduction in the lymphocyte count in the response to x-ray therapy. At the same time the amount of antibody on the cells appeared to reach lowest concentration of any time during his course. These variations may be chance variations in the disease and bear no relationship to x-ray therapy. However, exposure to x-ray has been shown to diminish antibody response in animals, and we have previously observed improvement in a patient with acquired hemolytic anemia<sup>9</sup> given x-ray therapy. With a method of assay available, further data may be obtained on the effect of x-ray on the amount of antibody produced in acquired hemolytic anemia.

FIG. 1.—Survival time of transfused cells in patients with acquired hemolytic anemia and in patients with other types of hemolytic disease. Patients S, E, S, J, B, T, G all showed sensitization of the erythrocytes. Patients C, P, and A had congenital hemolytic jaundice, Mediterranean anemia, and paroxysmal nocturnal hemoglobinuria.

## II The Longevity of Transfused Cells

Observations of the survival of normal transfused cells was made by the technique of differential agglutination in 6 of the 11 patients. The results of these observations are shown in figure 1. In all 6 cases the destruction of the transfused cells was several times the rate of destruction of transfused cells in normal individuals and in patients with other types of hemolytic disease. Observations in figure 1 include congenital hemolytic jaundice, Mediterranean anemia, and paroxysmal nocturnal hemoglobinuria.

In three additional patients in this series (Nos. 2, 4, 5), repeated transfusions were necessary, and it soon became apparent from simple calculation that the transfused red cells were being destroyed rapidly because of the transitory effect on the severity of the anemia. In each case enough red cells were given during the space of a few days to replace entirely the patient's cells and to produce a

normal or greater than normal circulating red cell volume. Since the anemia quickly developed again in the absence of blood loss, it must be assumed that the transfused, as well as the patient's own red cells were rapidly destroyed. In one of these patients (No. 5) exhibiting very marked spherocytosis, it was shown previously<sup>4</sup> that transfused cells showed a tendency toward spherocytosis and an increase in hypotonic fragility within forty-eight hours after injection.

In the remaining 2 patients, no data were obtained as to the longevity of transfused cells.

FIG. 2.—Curves of hypotonic fragility in 12 patients with acquired hemolytic anemia. The central dotted line is the average of 30 control determinations while the lateral lines represent the extremes. H S, H J and J F were patients who continued to have active disease after splenectomy. There is evidence that the curve of hypotonic fragility was close to normal prior to splenectomy. C A showed the most severe disease prior to splenectomy. One H S showed a normal fragility curve even though the disease was very active.

### III Susceptibility to Hemolysis in Hypotonic Solution

Representative samples of the quantitative curves of hypotonic fragility are shown in figure 2. An average control curve is shown and the limits of variation of some 30 control curves are also represented. It can be seen that most of our patients with acquired hemolytic anemia had curves of hypotonic fragility which were increased above average but were close to or within the widest limits of normal variation by the method employed. In one patient (C A) with active hemolytic anemia and an output of 2080 mg. of fecal urobilinogen per day, the curve of hypotonic fragility was identical with a normal curve done at the same time.

On the other hand, 3 patients in this series (H S, J F, C A) and one other patient (H J), reported elsewhere,<sup>9</sup> showed curves of hypotonic fragility which were considerably increased above the normal range. Three of these 4 continued to have chronic hemolytic anemia following splenectomy. The fourth patient (C A) showing greatly increased hypotonic fragility of the red cells had by some criteria the most severe hemolytic anemia in the series and died without splenectomy.

Sweeping conclusions cannot be drawn from these observations, but it is evident that the susceptibility of circulating erythrocytes to hemolysis in hypotonic solution may be quite normal in the presence of active disease even with sensitive methods of measurement. The increase in hypotonic fragility when the disease persists following splenectomy suggests that the spleen *in situ* may remove the spherocytic cells from the circulation and keep the curve of hypotonic fragility in

TABLE 8 — *Platelet and Leukocyte Counts before and after Splenectomy in Patient who Showed Thrombocytopenia or Leukopenia along with Active Hemolytic Anemia*

Patient	Platelets		Leukocytes	
	Before splenectomy	Following splenectomy	Before splenectomy	Following splenectomy
C S	70,000	100,000	2,000	7,000
J F	60,000	70,000	13,000	18,000
F R	10,000	45,000	9,500	6,700
O W	12,000	675,000	1,700	8,000
D B		190,000		Normal
	35,000 106,000	Normal	5,000	

the peripheral blood close to normal range unless the disease becomes very active, as was the case in the patient (C A) who died without splenectomy.

#### IV *Thrombocytopenia and Leukopenia*

Five patients in this series had persistently low platelet counts prior to splenectomy, and 2 of the 5 had a marked degree of leukopenia. These findings are summarized in table 8, which shows representative platelet and leukocyte counts before and after splenectomy.

Only one of the patients with thrombocytopenia had clinical manifestations of purpura. This patient (F R) was hospitalized because of purpura, and the hemolytic anemia was not suspected at first. The remaining 4 patients did not exhibit purpuric manifestations, although the platelet count was below 60,000 per cu mm in several determinations. Following splenectomy, the platelet counts of three of the five patients rose to a normal level or above, concomitant with a subsidence of the hemolytic process. The patient with thrombocytopenic purpura and hemolytic anemia continued to have few platelets in the peripheral blood with platelet counts of 10,000 or less for the remaining two months of her pregnancy and during the postpartum period. In spite of the failure of her platelets to rise, there appeared to be a definite improvement in the purpura after operation, and

the bleeding time fell to a normal range. The hemolytic anemia improved slowly, beginning about one month following splenectomy, but was still active at the time of delivery. She was delivered without incident with one transfusion given at the time of delivery. The platelet count one year later was still only 50,000 per cu mm, and there was evidence of some sensitization of the erythrocytes, though the hematocrit was 40 and the reticulocytes were 0.5 per cent.

A second patient (J. F.) continued to exhibit a persistent thrombocytopenia following splenectomy. The chronic hemolytic anemia also persisted without real remission, although there was evidence of some decrease in severity following operation.

Both patients with leukopenia showed a prompt and consistent elevation of the leukocyte count to normal range following splenectomy, along with a response of the other blood elements.

### DISCUSSION

The demonstration of the direct relationship of the amount of adsorbed antibody to the rate of destruction of red cells is another step in our understanding of the pathogenesis of acquired hemolytic anemia. Activity of the disease is associated with evidence of maximal adsorption of the immune body, whereas remission in the hemolytic activity is, in the main, associated with distinctly less adsorbed immune substance. So far we have not observed the complete disappearance of the abnormality, even in patients who have been in remission for a year or more, which explains perhaps why relapse of this disease occurs so readily. The immediate effect of splenectomy when it is successful in producing a remission appears to be brought about by a sharp reduction of the amount of adsorbed sensitizing agent on the cell. This suggests that the spleen is the principal site of production of the sensitizing agent. Wagley and co-workers<sup>10</sup> have recently been able to demonstrate the persistence of the sensitizing agent in the washed pulp of spleens from patients with acquired hemolytic anemia. The failure of splenectomy to produce a remission in some patients is evidently due to the production of sufficient hemolysin in other lymphatic or reticulo-endothelial tissues to keep the disease active. Even when the hemolytic process continues there is usually evidence that splenectomy has diminished its severity. This observation implies that some proportion of the total quantity of hemolysin is always produced in the spleen.

The exact nature of the hemolysin is still not entirely clear. The chief question seems to be whether or not it is a true immune body or some entirely different as yet unknown, type of variant of normal plasma protein. Evidence is needed to show that the hemolytic agent is a specific immune response to an antigen common to erythrocytes. Perhaps a complex of some component of the red cell and a foreign substance such as a virus or medication provides the necessary antigenic stimulus. This explanation would be more clear-cut if it were shown that hemolytic anemia is definitely associated with sulfonamide medication exhibited the same evidence of sensitization of the erythrocytes. In our series one patient received gold therapy prior to and during the onset of her disease but this cannot be regarded as a

than suggestive evidence that erythrocyte antibody production may be stimulated by a medication, since hemolytic disease is not generally reported as a complication of gold therapy.

Another group of anemias which require further study with the special immunologic technic are the so-called symptomatic hemolytic anemias. This term is used to describe hemolytic disease associated with a large variety of disease states including lymphomas, leukemias and cirrhosis. So far we have studied only one such patient, but the mechanism of hemolysis seems to be the same as in other patients with acquired disease. It is of interest that diseases of lymphocytic tissue, which is known to be active in the production of antibodies, are associated with hemolytic anemia and that treatment of the underlying disease by x-ray is said to be helpful in controlling the hemolytic process.<sup>11</sup> It is probably significant that an improvement in the anemia and transient decrease in the amount of adsorbed antibody followed x-ray therapy of the lymphatic leukemia in our patient.

In the study of patients with atypical or acquired hemolytic anemia several technics should be employed to determine the presence or absence of adsorbed antibody. Our experience, with two separately prepared anti-human serum rabbit sera, indicates that specificity may vary and that two or more sera should be used to demonstrate the presence of adsorbed antibody. Less specific but equally sensitive methods should also be used in conjunction with the Coombs test. Washed erythrocytes should be suspended in human serum and in 30 per cent beef albumin, incubated, subjected to centrifugation and inspected for agglutination before the possibility of sensitization is discarded. The same technics should be employed in an attempt to demonstrate free antibody in the serum. Normal cells will adsorb the free immune body if present in the patient's serum and become agglutinable in the Coombs reagent or in beef albumin. However, our efforts to demonstrate free antibody in the patient's serum have been inconstant as opposed to the consistency with which it has been demonstrated to be adsorbed on circulating cells.

The exact mechanism of cell destruction brought about by the antibody is not entirely clear. We have, as yet, no evidence that hemolysis occurs as a result of lysis with the fixation of complement. There is, on the other hand, evidence to show that destruction of sensitized cells is relatively slow. Observations with antiglobulin serum indicate that the great majority of cells in the peripheral blood are sensitized, since nearly all are involved in the agglutination. However, studies of pigment excretion and observations of longevity of transfused cells indicate a survival time of several days for the average cell. It is evident that sensitization does not bring about immediate destruction.

There is evidence from transfusion experiments to show that sensitization is reversible, since cells from patients with acquired hemolytic anemia may have a normal survival time when transfused into a normal individual.<sup>1</sup> It has also been demonstrated that A cells sensitized by B agglutinin are not irreversibly damaged and exhibit a normal survival time after being used in a transfusion.<sup>12</sup> We have observed that transfused cells which have been in the patient's circulation for several days prior to splenectomy and demonstrated to be involved in the hemolytic process show a normal rate of disappearance when splenectomy has produced a

remission. We may conclude that sensitization brings about cell destruction slowly over the course of days and that it does not immediately damage the red cell irreversibly.

If the sensitized cells are susceptible to agglutination *in vivo* we have an explanation of cell destruction, since it has been shown that the injection of a simple agglutinin, such as Concanavalin A, will produce a hemolytic anemia in animals.<sup>12</sup> We have not observed agglutination of red cells from patients with acquired hemolytic anemia *in vivo*, but agglutination does occur under optimum conditions *in vitro*. When the washed cells are suspended in whole human serum and subjected to light centrifugation, agglutination is usually observed. The reaction is qualitative, but we have the impression that the intensity of the agglutination is proportional to the degree of sensitization as measured by the anti-human-serum serum technic as described above. In several instances, cells from patients in mild or inactive phases of the disease failed to agglutinate when centrifuged in whole serum, probably because of a lack of sufficient concentration of antibody on the cell surface.

It seems probable that agglutination of sensitized cells *in vivo* is the most important mechanism in cell destruction. Agglutination produces stasis of cells which leads to increased osmotic and mechanical fragility and probably susceptibility to phagocytosis. If a critical concentration of immune globulin on the cell surface is necessary to produce agglutination *in vivo* we have an explanation for the cessation of hemolysis in the quiescent state since the amount of antibody on the cell appears to be considerably reduced. The suggestion that a certain concentration of immune body on the cell surface is necessary for cell destruction *in vivo* may explain the absence of hemolytic disease in the newborn even when maternal sensitization has occurred and there is maternal-fetal incompatibility. In these instances it is possible that the concentration of immune substance on the baby's cells may not be great enough to produce agglutination and hemolysis.

The implications of the association of thrombocytopenia and leukopenia with acquired hemolytic anemia are clear. It strongly suggests that the leukopenia and thrombopenia in these patients is due to the presence of an immune body with a broader range of activity than the red cells or to a separate immune substance or substances more specific for platelet and white cell tissue. The latter explanation is more likely since there is no correlation between severity of the hemolytic process and the degree of thrombocytopenia or leukopenia. It is possible that a similar mechanism will be found for thrombocytopenic purpura and splenic neutropenia which occur as single disease states unaccompanied by hemolytic anemia. Previous observations of the occurrence of leukopenia, thrombocytopenia and hemolytic anemia in the same patient were made by Wiseman and Doan<sup>14</sup> in their original report of primary splenic neutropenia, and by Dameshek and Estren.<sup>15</sup> The latter authors refer to these cases as "hypersplenic hemolytic anemia" and a correlation of the leukopenia and thrombocytopenia on the basis of an unusual degree of inhibition upon the bone marrow. Such cases often show a remarkable response to splenectomy. It is probable that the hemolytic anemia in the type of acquired variety, especially since a family history of hemolytic disease is not

ing A patient with splenic neutropenia described by Rogers and Hall<sup>15</sup> showed thrombocytopenia and a mild anemia with slight polychromatophilia, normoblasts in the peripheral blood and elevation of the indirect reacting serum bilirubin Fisher<sup>16</sup> recently commented on the presence of leukopenia and thrombocytopenia in one of a series of patients with acquired hemolytic anemia

The association of thrombocytopenia with acquired hemolytic anemia seems to be more common than the occurrence of a panhematopenia In 1941 we observed severe thrombocytopenia with fatal termination in a 31 year old man who had had splenectomy three years previously for hemolytic anemia that was evidently of the acquired variety since there was no past or family history of hemolytic disorder A mild thrombocytopenia was present with the severe anemia prior to surgery There was response of both anemia and thrombopenia following operation, and he was well until the development of purpura four years later in which blood platelets were close to the zero level He died of a cerebral hemorrhage and autopsy showed no evidence of an accessory spleen In 1942 one of us studied a patient<sup>17</sup> with acquired hemolytic anemia who exhibited severe thrombocytopenia during most of seventeen weeks of hospitalization Platelet counts became normal for a short interval following splenectomy, but the thrombocytopenia recurred along with continuing hemolysis

The patient in the present series who showed clinical purpura during pregnancy seems to represent a transition between acquired hemolytic anemia and classical thrombocytopenic purpura in that the bleeding tendency and anemia were both important clinical features To complete the transition from one disease to the other we have recently studied a young woman with idiopathic thrombocytopenia who showed a relatively mild anemia which may have been caused by the persistent vaginal bleeding However, her red cells gave a positive test with the anti globulin serum in a dilution of 1-40 on several occasions Evidence of red cell sensitization ceased abruptly and completely following splenectomy, although the thrombocytopenia continued with some improvement over the course of months

The various explanations of the cause of primary thrombocytopenic purpura resolve into two principal points of view The first holds that thrombocytopenia occurs because of deficient formation of platelets in the bone marrow Dameshek and Miller (18) found an increased number of megakaryocytes in the marrow which were qualitatively abnormal in that they did not seem to be producing platelets They postulated a hormonal influence of the spleen in depressing platelet formation Excessive destruction of platelets, particularly in the spleen, is the alternative explanation for deficiency of platelets in the peripheral blood Principal exponents of this view are Doan and his co-workers, who have observed excessive phagocytosis of platelets in supravital preparations of splenic tissue<sup>19</sup> Excessive phagocytosis is also advanced as the explanation of primary splenic panhematopenia with hemolytic anemia, thrombocytopenia and leukopenia

Abnormal phagocytosis of damaged blood elements probably does occur, but we doubt if the macrophages of the intact spleen have the capacity to ingest and digest the amount of cellular elements necessary to produce a severe panhemato-

penia in view of the functional capacity of the marrow. The suggestion that an accessory spleen consisting of a few grams of tissue is capable of doing the same thing seems less plausible.

If thrombocytopenic purpura is due to the formation of an antibody-like substance similar to that found in acquired hemolytic anemia both deficient formation and excessive destruction may be important in producing the extreme degrees of thrombocytopenia sometimes observed. Sensitized platelets may be susceptible to agglutination, and phagocytosis and the presence of an anti-platelet antibody in the circulation may damage the cytoplasm of the megakaryocyte so as to inhibit the formation of platelets.

In view of the possibility of a common etiologic mechanism for acquired hemolytic anemia and thrombocytopenic purpura, it is worth noting that the available data as to the effect of splenectomy in the two diseases shows a similarity. In both conditions the effect of splenectomy is uncertain. It is usually beneficial to some degree, but in only one half to two thirds of the patients is remission complete.<sup>20-22</sup> Relapse after a remission has been observed in both groups of patients.

#### SUMMARY AND CONCLUSIONS

1. Observations of 11 patients with acquired hemolytic anemia are reported.
2. In contrast to patients with congenital hemolytic jaundice, all patients in this group exhibited evidence of sensitization of their erythrocytes by an antibody-like agent. In all patients studied there was abnormal destruction of transfused cells *in vivo*.
3. The sensitizing agent was found to be adsorbed on the erythrocytes when it could not be demonstrated in the serum. A rough method of assay of the amount adsorbed was devised by making serial dilutions of the anti-globulin serum. With this technique a fairly consistent correlation was found between the amount of antibody on the cell and activity of the disease.
4. Splenectomy when successful appears to exert a curative effect by sharply reducing the amount of antibody substance on the cell. Patients who had not responded to splenectomy in the past showed evidence of saturation of their cells with adsorbed antibody. The erythrocytes of patients who had responded to splenectomy and were in remission when studied showed distinctly less antibody on the cell by the same technique.
5. Two patients were observed to enter spontaneous remission after a long period of activity. The onset of remission in both was associated with a decrease in the amount of adsorbed immune body. However, one patient has shown evidence of return of antibody production without immediate recurrence of the hemolytic anemia. This inconsistency is not explained.
6. The tendency toward spherocytosis as measured by increased osmotic fragility may or may not be present in acquired hemolytic anemia. Prior to splenectomy the most marked increase in hypotonic fragility was observed in the patient with the most active disease. Continued activity of the disease following splenectomy was

productive of the most extreme increases in spherocytosis. This suggests that the spherocytic cells are removed from the circulation by the spleen.

7 Agglutination of red cells when the amount of adsorbed antibody reaches a critical level, together with such other phenomenon as stasis, spherocytosis, increased mechanical fragility and possibly phagocytosis probably explain the increased cell destruction.

8 The occurrence of definite and sustained leukopenia with neutropenia and thrombocytopenia in several patients with hemolytic disease due to an immune body agent raises questions as to the etiology of classic thrombocytopenic purpura and of splenic neutropenia. Patients have been observed who seem to represent transition forms between acquired hemolytic anemia and thrombocytopenic purpura. Abnormal immune mechanisms could account for both excessive destruction of platelets and deficient formation.

# SEROLOGIC METHOD OF PURIFYING BLOOD GROUP A SUBSTANCE

By WILLIAM C. BOYD, PH D., AND ROSE M. REGUERA, B S

THE USE OF blood group A and B substance for the conditioning <sup>1</sup> of group O blood for transfusion (i.e., partially neutralizing the anti-A and anti-B agglutinins in the group O plasma) has today acquired considerable importance, and would probably continue to be used in time of war <sup>18</sup> The A substance used for this purpose has been prepared from hog stomach linings, and the B substance from horse stomachs (this B substance having also some A activity) Representative methods of preparation are described by Kabat <sup>10</sup>

Regarding any material to be added to blood before it is used for transfusion, the question of purity is, of course, important When the use of these A and B substances was first introduced, little was known about their chemical composition, although information suggesting their safety was available And, in fact, the work of Kabat <sup>9</sup> has since shown that the early materials were certainly mixtures, containing some active and some inactive material It was felt at the time that the preparation of a material known to be 100 per cent pure, even in small amounts, would be worth while, as it would provide a standard of potency with which materials offered for large scale use could be compared

It is, of course, possible that chemical methods alone could yield material which would be completely pure and 100 per cent reactive, and some of Kabat's later work suggests that he has come very close to achieving this aim Nevertheless, it seemed desirable to test an entirely different method of preparation, one in which the method of purification was primarily serologic The present communication deals with the results obtained by application of this method

It has long been known <sup>16</sup> that it is often possible, by injecting rabbits with human erythrocytes of blood group A, to obtain precipitating antibodies for A substance It was shown <sup>3, 10</sup> that such antibodies would precipitate the A substance prepared from hog stomachs It is obvious that this affords a delicate and specific method of separating serologically active A substance from inactive carbohydrates which are present and which are similar in their chemical properties If the precipitate which results when a crude preparation of group A substance and a precipitating antibody produced by the injection of human group A erythrocytes is washed thoroughly with saline, it will contain only serologically active A substance, anti-A precipitin (a modified rabbit globulin), and possibly traces of lipids and various components of complement <sup>8</sup> Removal of the antibody should leave a group A substance of a high degree of purity

## METHODS

<sup>1</sup> *Production of antisera* Rabbits were injected three times weekly with one cc of a 30 per cent suspension in saline of washed human erythrocytes of group A To avoid possible variations due to indi-

From the Department of Biochemistry Boston University School of Medicine Boston Mass  
This investigation was supported by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health U S Public Health Service

vidual differences in blood group antigens the cells of a single individual (WCB) were always employed. Bleedings showed that 15 out of 20 of the animals had produced group-specific precipitins within five weeks after the injections were started. The preliminary tests were done by the interfacial technic using crude A substance. The pooled active sera were assayed for antibody content by the method of optimal proportions.<sup>8</sup> The results indicated a content of antibody nitrogen varying from 0.2 to 1.0 mg. per cc.

2. *Source of A substance.* The A substance used was a preparation of the Eli Lilly Company, designated as intended for laboratory work only (Lot numbers R 15 and 330). Analytical data for the latter preparation are given by Kabat.<sup>9</sup>

3. *Preparation of specific precipitates.* After determination of the optimal proportions ratio of a given pool of serum (previously filtered) a solution of A substance containing the calculated optimal amount plus a 10 per cent excess was added. The mixture was allowed to stand in the icebox overnight and the precipitate centrifuged off and washed until the washings were free from protein as judged by the absence of opalescence when saturated with picric acid. From three to five washings were usually required.

4. *Treatment to remove the antibody.* Various treatments designed to remove the antibody from the antibody antigen complex were tried using a total of 18 samples of crude blood group A substance totalling 362.5 mg. They included (a) digestion with trypsin (b) digestion with chymotrypsin (c)

digestion with papain activated with cysteine hydrochloride<sup>11</sup> (d) treatment in the Waring Blender with chloroform and amyl alcohol<sup>12</sup> (e) treatment at room temperature with 90 per cent phenol<sup>13</sup> (f) treatment at 100 C. with 90 per cent phenol (g) treatment with 0.25 N trichloroacetic acid (h) subjection to pressures of 9000 atmospheres<sup>4</sup> for twenty-four hours (i) digestion with papain followed by treatment with half-saturated ammonium sulfate or by treatment with 12 per cent sodium sulfate or by treatment with trichloroacetic acid or by treatment with 90 per cent phenol (j) denaturation by heating to 100 C. for one hour followed by papain digestion (k) heating to 55 C. in ethylene glycol. After treatment by the above methods the material was precipitated by the addition of an excess of alcohol, centrifuged, the soluble material taken up in saline or water, reprecipitated and redissolved in saline. The solution was then tested for A activity by the inhibition technic<sup>14</sup> using the original material for a control (see table 1).

## RESULTS

None of these methods, unfortunately, yielded a product which was any more active than the starting material and at the same time completely soluble in saline. Methods (i) (papain followed by phenol) and (h) (high pressure) were, on the whole, the most successful in denaturing the antibody and releasing an active antigen. Nevertheless, the resulting products were never more active than the starting material, and were often less soluble in saline. The phenol method uniformly gave products insoluble in saline, which were, moreover, only 1/100 as active as the starting material. Method (i) (papain followed by phenol) gave

product which was soluble with some difficulty, but only 1/10 as active as the starting material. The other methods were even less successful, for the resulting products were either inactive or insoluble or both.

### DISCUSSION AND CONCLUSIONS

At the time this work was begun, no estimate was possible of the percentage of the crude A substance which was specifically active. It was provisionally (and, as it proved, incorrectly) estimated that the active material did not amount to over 5 per cent at the most. If this had been correct, it is likely that one or more of the above methods would have resulted in a significant degree of purification. From Kabat's<sup>9</sup> later results, however, it is now apparent that over half of the material was serologically active, and consequently that no great degree of purification, from the serologic point of view, remained to be accomplished. Kabat's work also suggests that chemical methods have been equal to the task of producing material nearly or perhaps quite serologically pure.

The decreased solubility of the A substance after it had been precipitated with antibody and subjected to the above treatments could possibly be explained by the assumption that some of the polar groups of the A substance remained in combination with fragments, of undetermined size, of the antibody, since none of the treatments rendered it less soluble, when applied to solutions of A substance directly.

It would seem that none of the above methods offer an ideal solution to the problem of completely eliminating the antibody from a compound of antibody and antigen, even though the blood group A substance, used in these experiments, is chemically much more stable than most antigens. The converse problem, of removing *some* relatively pure antibody from an antibody-antigen compound, leaving some insoluble antibody-antigen compound to be discarded, is obviously much easier, and has been solved for several systems by various workers.<sup>6, 7, 11, 14</sup>

# HEMOLYTIC REACTIONS PRODUCED IN DOGS BY TRANSFUSION OF INCOMPATIBLE DOG BLOOD AND PLASMA

## I SEROLOGIC AND HEMATOLOGIC ASPECTS

By LAWRENCE E. YOUNG, M D, DONALD M. ERVIN, M D, AND  
CHARLES L. YUILE, M D

HEMOLYTIC transfusion reactions occur more frequently than is generally appreciated and their incidence can be expected to increase for some time as the distribution of blood is facilitated. Many are doubtless overlooked because the outward manifestations may not be particularly striking, especially in anesthetized patients and in certain recipients transfused with plasma or with blood from universal donors. Despite the increasing importance of such reactions, their pathologic physiology remains poorly understood and cannot be adequately explored in human subjects. Consideration of these facts stimulated the authors to make observations on planned hemolytic reactions in dogs with the hope that the results might find general application in the field of immuno-hematology, and that they might throw light on the behavior of the kidney when subjected to certain types of insult.

The purpose of this paper is to describe preliminary serologic and hematologic observations on reactions produced in dogs by transfusion of incompatible whole blood and plasma. Typical experiments are cited to illustrate the usefulness of iso-immune systems in the dog in making quantitative studies of hemolytic phenomena. Alterations in renal physiology observed during these experiments are described in an accompanying report.<sup>1</sup>

## HISTORICAL

### *Individual Differences among Bloods of Mammals other than Dogs*

In 1900 Ehrlich and Morgenrath<sup>2</sup> found that when one goat was injected with the blood of another goat immune isolytins developed and by using such iso-immune serum a number of varieties of goat blood could be differentiated. Since that time other investigators have employed similar methods in demonstrating individual differences in the blood of other mammals. <sup>3</sup> Ottenberg and Thalheimer<sup>4</sup> demonstrated immune iso-antibodies in the serum of repeatedly transfused cats and these authors described the course of events during hemolytic reactions following injections of incompatible whole cat blood. Their findings included hemoglobinemia, hemoglobinuria, oliguria, glycosuria, hemoglobin casts in the urine, jaundice, erythrophagocytosis and leukocytosis.

### *Individual Differences among Dog Bloods*

In 1910 von Dungern and Hirschfeld<sup>5</sup> used iso immune sera to distinguish two agglutinogens and four groups among dog bloods but their observations and the few described by other investigators since 1910 have by no means completely clarified the pattern of individual differences in this species.

---

From the Departments of Medicine and Pathology, The University of Rochester School of Medicine and Dentistry Rochester, N. Y.

The studies described in this report were conducted under a contract between the University of Rochester and the Office of Naval Research. This paper was presented in abridged form at the Congress of the International Society of Hematology, Buffalo, New York, August 26, 1948.

Ottenberg, Kaliski and Friedman<sup>6</sup> demonstrated what appeared to be naturally occurring iso-hemagglutinins and hemolysins in dogs. The reactions described were for the most part weak and variable but it is nevertheless significant that potent iso-hemolysins developed after repeated transfusions of but it is nevertheless significant that potent iso-hemolysins developed after repeated transfusions of agglutinable cells and not after transfusions of non agglutinable cells. Dogs whose serum appeared to contain naturally occurring iso-antibodies were transfused with apparently incompatible whole blood by use of the direct artery to vein technique. Hemolytic reactions were observed after repeated transfusions but in only one instance did such a reaction occur after the first transfusion. The recipient in this case had previously been used as a donor and it is possible that this dog was immunized by cells which entered its circulation to some extent while the artery to vein anastomosis was intact. The sequelae of incompatible transfusions in dogs were similar to those observed by Ottenberg and Thalhimer<sup>4</sup> in cats. A finding of considerable interest was the appearance of many nucleated and polychromatophilic red blood cells which in one case persisted in the recipient's circulation for five weeks. This change was attributed to the toxic effect of incompatible blood on the bone marrow.

Melnick, Burack and Cowgill<sup>7</sup> and Melnick and Cowgill<sup>8</sup> found iso-hemagglutinins and hemolysins in the serum of dogs after repeated injections of erythrocytes during the course of plasmapheresis experiments. The immune iso-antibodies reacted with red cells from about 50 per cent of the dogs available to these observers and the reactions did not appear to be related to sex or breed. In their experience the development of incompatibility was one sided in that dogs designated by them as type A were capable of producing antibodies against cells from dogs of type B while B dogs did not produce antibodies when transfused with A cells. Salivation, vomiting, labored respirations, incontinence of urine and feces, prolonged clotting time and hemoglobinuria were observed in immunized A dogs during hemolytic reactions to the transfusion of B cells.

Holman, Mahoney and Whipple<sup>9</sup> and Wright<sup>10</sup> described similar reactions as complications of plasmapheresis and Wright found antibodies in the sera of 3 recipient dogs which reacted with cells of 7 members of a group of 11 donor dogs. Hahn and Bale<sup>11</sup> also encountered hemolytic reactions while measuring circulating red cell mass in dogs by transfusion of cells tagged with radioactive iron. They found moreover, that all of the new isotopic cells if incompatible, usually disappeared from the circulation of the recipient dog within ten minutes after transfusion. Miller, Robscheit Robbins and Whipple<sup>12</sup> observed hemolysis of recipient dogs' cells following transfusions of plasma from a dog that might have been immunized by previous injections of dog blood.

## METHODS

Dog iso-antibodies were titrated by mixing equal volumes (usually 0.1 ml.) of serial two-fold dilutions of serum with 5 per cent suspensions of dog cells in fresh unheated autologous serum. Immune serum was inactivated by heating at 56°C. for thirty minutes and was routinely diluted with saline, since it was found that titers against cells suspended in unheated serum were invariably the same regardless of whether the antiserum was diluted with saline or with normal dog serum. Titers were maximal when fresh normal dog serum was used either as a suspension medium for the cells or as a diluent for the antiserum and were not further enhanced by employing normal serum both as a medium for suspending cells and as a diluent for the antiserum.

After standing fifteen minutes at room temperatures of 23-27°C. the tubes were centrifuged at 1000 RPM for one minute. The cells were then gently but thoroughly resuspended and examined over a well illuminated concave mirror. Titers were expressed in terms of the final dilution of antiserum in the last tube showing agglutination. Agglutinated cells were rapidly hemolyzed in tubes containing high concentrations of antibody and complement but in the last tubes of any given series the agglutinated cells seldom hemolyzed appreciably during the fifteen minute period. Nonspecific hemolysis was minimized by carrying out the titrations at room temperature rather than at 37°C. and by centrifuging the tubes after allowing them to stand for a relatively short period (fifteen minutes).

\* The ability of certain dog antisera to agglutinate dog erythrocytes is enhanced by the presence of a heat labile component of normal dog serum as described in a separate report in the literature. This has thus far been observed only in sera having so-called anti-D or canine A antibodies. The heat labile component of complement has thus far been found only in sera having so-called anti-D or canine A antibodies. The heat labile component of complement has thus far been found only in sera having so-called anti-D or canine A antibodies.

† Only D or canine A antibodies have thus far been found to enhance the hemolytic activity of complement. Other dog isoantibodies that have been tested have not been found to enhance the hemolytic activity of complement.

*Complement* was measured by mixing serial two-fold dilutions of fresh dog serum in volumes of 0.3 ml with 0.2 ml volumes of sensitized sheep cells prepared by Wadsworth's<sup>14</sup> method. The tubes were placed in a water bath maintained at 37 C, shaken at five minutes and examined for hemolysis at fifteen minutes. The 50 per cent end point was then computed by the method of Heden<sup>15</sup> which takes into account the degrees of hemolysis in the last four tubes showing reaction.

All *transfused blood* was drawn from normal donor dogs within one hour prior to the beginning of transfusion and was injected into one of the jugular veins of the unanesthetized recipient dogs at rates of 3 to 7 ml per minute. A saturated solution of sodium citrate (1.0 ml per 100 ml of blood) was used as an anticoagulant in all but two transfusions and in these two instances heparin was employed. Samples of blood from recipient dogs were drawn from the jugular veins with great care to minimize artificial hemolysis. It was found advantageous to coat the inner surfaces of syringes and needles with silicone in order to prevent coagulation during the withdrawal and delivery of large samples into multiple containers.

The concentration of *hemoglobin* in plasma was measured by the pyridine hemochromogen method of Flink and Watson<sup>16</sup> and bilirubin was quantitated by Ducci and Watson's<sup>17</sup> modification of the method of Malloy and Evelyn.<sup>18</sup> *Osmotic fragility of erythrocytes*,<sup>19</sup> *coagulation time of whole blood*<sup>20</sup> and *prothrombin concentration*<sup>21, 22</sup> were determined by procedures described elsewhere. *Platelets* were enumerated according to Wintrobe's<sup>23</sup> description of the Rees-Ecker technic. *Differential agglutination of dog erythrocytes* (Ashby technic) was carried out by the method of Young, Platzer and Rafferty.<sup>24</sup>

*Reticulocytes* were stained by mixing a small drop of oxalated blood on a glass cover slip with a large drop of 0.2 per cent suspension of brilliant cresyl blue in 0.6 per cent solution of sodium chloride. The two drops were mixed for thirty seconds with a toothpick, after which time another cover slip was applied and smears were pulled, dried and counterstained with Wright's stain to make permanent preparations.

Blood used for *enumeration of leukocytes* and for preparation of Wright's stained smears on glass cover slips was taken from a small incision in the marginal ear vein and was used without addition of any coagulant. Smears thus prepared were employed for *differential leukocyte counts* and were routinely examined for the presence or absence of spherocytosis and erythrophagocytosis. Both glass and plastic cover slips were used in making wet preparations of oxalated, defibrinated or heparinized venous blood to be examined for the presence or absence of *spherocytosis*, *erythrophagocytosis* and *hemagglutination*.

## EXPERIMENTAL OBSERVATIONS

### *Definition of Do-positive and Do-negative Dogs*

Our studies began with the demonstration of immune iso-hemagglutinins and hemolysins in the serum of a dog that had had a hemolytic reaction after a series of transfusions from several donors. Serum from this dog agglutinated and hemolyzed erythrocytes from about two-thirds of the dogs selected at random from the animal colony maintained by the University of Rochester School of Medicine and Dentistry.\* Cells reacting with this serum, or subsequently with other dog sera having similar specificity, were tentatively labelled *Do-positive*, while those that were neither agglutinated nor lysed were called *Do-negative*.

Further serologic studies on more than 400 dogs indicate that, in addition to the *Do* factor, there are at least three other antigenic factors present in various combinations in dog erythrocytes. The antigenic structure of canine red cells has

\* The assistance of Dr. F. S. Rohnsheit Robbins, Dr. Paul Rekers, Dr. Herbert Stokinger and others in the collection of specimens of dog blood is gratefully acknowledged. The previously cited observations of Holman, Mahoney and Whipple,<sup>9</sup> Wright,<sup>10</sup> Hahn and Bale,<sup>11</sup> and Miller, Rohnsheit Robbins and Whipple<sup>12</sup> were made in the Department of Pathology of the University of Rochester School of Medicine and Dentistry. Their experiences were to a considerable extent responsible for the decision of the authors to carry out the studies reported in this paper.

not yet been determined to our satisfaction but is now being explored more extensively and will be the subject of a later report. Our attention has until recently been devoted for the most part to the study of hemolytic transfusion reactions due to Do antibodies.

### *Iso-immunization of Dogs*

The immunization programs in three typical experiments are illustrated in figure 1. The top graph shows that antibodies were first detected eleven days after a single large transfusion of Do-positive blood into a Do-negative dog that had not been previously transfused. Rapid disappearance of the donated cells at the

FIG. 1—TYPICAL EXPERIENCES WITH IMMUNIZATION OF DO-NEGATIVE DOGS BY INTRAVENOUS INJECTION OF DO-POSITIVE WHOLE BLOOD

time of antibody development was demonstrated with the Ashby technique by employing potent anti-Do serum. In the middle graph it can be seen that three small injections produced antibodies within eight days in a dog previously transfused with dog bloods of unknown type. The bottom graph shows that an antibody developed only after 10 injections over a period of thirty-five days in a relatively refractory dog that had not been previously transfused. Still more refractory dogs have recently been encountered. For example, one dog developed an antibody only after 17 injections had been given over a period of one hundred thirty days.

### *Characteristics of Dog Iso-antibodies*

Do iso-antibodies have been found to fix complement both in vitro and in vivo, and it has been repeatedly observed that in the presence of complement

nated Do-positive cells are subsequently hemolyzed *in vitro* at rates depending upon the amounts of antibody and complement present. The Do and Rh systems in the dog and human species respectively appear to have a number of features in common. An important difference, however, is that Do-antibodies hemolyze Do-positive cells relatively quickly in the presence of complement while Rh antibodies hemolyze Rh-positive human cells very slowly if at all.<sup>26</sup> Under certain conditions Do-antibodies behave like incomplete Rh antibodies in that their attachment to erythrocytes can be demonstrated by developing tests employing anti-dog-serum rabbit serum and by the agglutination of sensitized cells when suspended in normal dog serum. Characteristics of dog iso-antibodies will be described in more detail in a separate report.<sup>12</sup>

### *Observations on Hemolytic Transfusion Reactions*

Serial observations have thus far been made during the course of twenty-three hemolytic reactions produced in 13 different recipient dogs by transfusion of

incompatible whole dog blood or plasma. Prominent manifestations observed during the periods immediately following transfusion are recorded in table 1 which, for purposes of the present discussion, requires no further comment.

### *Transfusion of Incompatible Whole Blood*

Figure 2 illustrates the manner in which the concentrations of hemoglobin and bilirubin rose and fell in the plasma of a Do-negative recipient after typical transfusions of Do-positive whole blood. When the recipient's anti-Do titer was 1:256 the peak of hemoglobinemia was nearly twice as high after a transfusion of only 100 ml of Do-positive blood as it was after a transfusion of 200 ml from the same donor into the same 15 kilogram recipient at an earlier date when the anti-Do titer was only 1:2. The hemoglobinemia curve was flatter when the recipient's titer was low and the volume of transfused blood was large. The less rapid destruction of donated cells *in vivo* under these circumstances was in keeping with the results of *in vitro* experiments. The concentration of hemoglobin in the plasma was nevertheless maximal within 10 minutes after this transfusion was completed, and it was maximal, or nearly so, at 5 to 10 minutes in most of the other experiments. Bilirubinemia, on the other hand, was maximal at 3 to 6 hours after each

transfusion of incompatible whole blood and in nearly every instance the concentration of bilirubin in the plasma had returned to the normal range within 24 hours.

Observations made before and after another typical transfusion of incompatible whole blood are recorded in figure 3. In this experiment, the donated corpuscles were tagged with radioactive iron\* and it was possible to show that these cells completely disappeared from the recipient's circulation within the first hour after the transfusion was completed. In fact, 84 per cent of the donated erythrocytes disappeared within 10 minutes after completion of the transfusion, or within 30 minutes after its start. In four other experiments employing tagged cells, nearly all of the donated erythrocytes disappeared within 30 to 90 minutes after com-

FIG. 2.—RELATIONSHIP OF HEMOGLOBINEMIA AND BILIRUBINEMIA TO ANTIBODY TITER AND VOLUME OF TRANSFUSION. The same Do-positive donor and immunized Do-negative recipient were used in both of these transfusions.

pletion of the transfusions. It is therefore little wonder that the hemoglobinemia curves differed so slightly from those obtained after intravenous injection of hemoglobin solutions, and that significant morphologic changes could not be detected in smears or wet preparations made from venous blood of the recipients. The very rapid disappearance of donated cells also explains the observation that only a barely measurable portion of the erythrocytes present in the recipient's circulation after such transfusions showed slightly increased osmotic fragility.

Surprisingly rapid disappearance of incompatible cells was further demonstrated

\* Drs. James A. Bush, John W. Hayden and Henry Tesluk assisted with the measurements of activity which were made by a modification of the donor cell dilution method of Bush and volume.

by using the Ashby technic after this transfusion and in six other similar experiments. In no case could agglutinable Do-positive cells be demonstrated after transfusion by mixing potent anti-Do serum with samples of recipient's blood. When the Ashby method was applied to the Do-anti-Do system after transfusion of compatible cells, on the other hand, donated Do-negative corpuscles were shown to survive for at least three months in the circulation of a Do-positive dog. This observation on the life span of canine erythrocytes is in accord with estimates made by other methods.

The amount of complement present in the circulation of the recipient dog declined abruptly during this transfusion of incompatible whole blood. In each of 10

FIG. 3.—SEQUELAE OF TYPICAL TRANSFUSION OF DO-POSITIVE WHOLE BLOOD INTO IMMUNIZED DO-NEGATIVE RECIPIENT (WEIGHT 15 KG.)

other similar experiments the decline was equally precipitous and after large transfusions, complement was barely detectable for about five hours. Post-transfusion specimens of serum were not anticomplementary, despite their high content of free oxyhemoglobin. At twenty-four hours and for several days thereafter, the titer of complement was frequently higher than before transfusion. The fall and subsequent rise in antibody titer noted after this transfusion were observed in some of the other experiments but with much less regularity than the changes in concentration of complement.

Fluctuations in total and differential nucleated cell counts after the typical transfusion just referred to are recorded in figure 4. The transient leukopenia, followed by leukocytosis, shift to the left and a shower of nucleated red cells, was observed after nearly all injections of incompatible whole blood. Erythrophago-

FIG 4.—FLUCTUATIONS IN TOTAL AND DIFFERENTIAL COUNTS OF NUCLEATED CELLS IN CIRCULATION OF IMMUNIZED DO-NEGATIVE RECIPIENT AFTER SAME TRANSFUSION PLOTTED IN FIG 3

cytosis (fig 5) was observed to a slight extent in smears of venous blood prepared during the first few minutes after such transfusions, but it was always necessary to search many microscopic fields before finding macrophages containing red cells. Wet preparations proved to be less satisfactory than fixed smears for detection of erythrophagocytosis. In none of the wet preparations of venous blood from recipient dogs was hemagglutination (suggesting intravascular agglutination) observed. Platelets became slightly less numerous for a few hours after injections of whole blood, and transient increases in coagulation time and decreases in prothrombin concentration\* were observed in some instances.

Electrophoretic studies\* were carried out on samples of plasma taken before transfusion, and at 30 minutes, 4 hours and 23 hours after a transfusion of 60 ml of incompatible whole blood. The only significant change in the patterns was the appearance at 30 minutes of a large peak with a mobility between that of fibrinogen and beta globulin. The area of the peak corresponded with the concentration of hemoglobin in the plasma as determined by the pyridine hemochromogen method. Light transmitted through the cell in the region of this peak showed the absorption bands characteristic of oxyhemoglobin. At 4 hours the height and area of the peak had slightly diminished and at 23 hours the peak had almost disappeared. It is worthy of note that at 30 minutes and at 4 hours the hemoglobin migrated with an abnormally low mobility, but at 23 hours the mobility of hemoglobin had returned to normal.

Nearly all post-transfusion specimens of plasma were examined with a hand spectroscope in an effort to detect the presence of methemoglobin or methemalbumin. The absorption bands were invariably those of oxyhemoglobin, absorption in the red portion of the spectrum was not observed.

The concentrations of sodium and potassium in the serum were not significantly increased after transfusions of incompatible whole blood.\* These negative findings are of interest in view of the relatively high content of sodium and low content of potassium in dog erythrocytes as compared with human red cells.<sup>27</sup> Muirhead et al.,<sup>28</sup> on the other hand, have reported high concentrations of potassium in the serum of human recipients following transfusions of incompatible human cells.

### *Transfusion of Incompatible Plasma*

When Do-positive dogs were transfused with plasma from immunized Do-negative dogs the course of events was distinctly different from that seen after administration of incompatible whole blood. It is evident in figure 6 that after transfusion of 45 ml of plasma with an anti-Do titer of 1:256, the concentration of hemoglobin in the plasma of the 16 kilogram Do-positive recipient did not reach its peak until the fifth hour. Hemoglobinemia persisted for more than 72 hours and hyperbilirubinemia for more than 24 hours. In order to sustain this dog's life it was necessary to give 260 ml of compatible Do-negative whole blood 5 hours after injection of the incompatible plasma. Despite this large transfusion, the recipient dog's hematocrit gradually fell to 22 per cent on the ninth day, after which time

\* Determinations of prothrombin concentration were made by Dr. Ralph F. Jacox; electrophoretic studies by Dr. Eric Alling; and measurements of serum sodium and potassium by Dr. Jacob W. Holler.

Fig 6—SEQUELAE OF TRANSFUSION OF ANTI DO PLASMA INTO DO POSITIVE RECIPIENT (WEIGHT 16 Kg) Compatible Do-negative whole blood was given 5 hours later to sustain life

Fig 7—LATERAL PLOT OF OSMOTIC FRAGILITY OF DO-POSITIVE RECIPIENT'S CELLS AFTER THE TRANSFUSION OF ANTI DO PLASMA PLOTTED IN FIG 6

the hematocrit began to rise due to the formation of new cells. The peak of the reticulocyte response was reached on the thirteenth post transfusion day. It is of interest that there was as only a moderate decrease in the titer of complement.

during the first five hours after this transfusion of plasma and that at no time could the donated Do-antibodies be demonstrated in the recipient dog's serum. The osmotic fragility of the recipient dog's erythrocytes, as observed over a period of four weeks after transfusion of incompatible plasma, is plotted laterally in figure 7. Spherocytosis (fig. 8) and increased fragility were evident for twenty days and the period of marked increase in fragility corresponded well with the nine-day period of falling hematocrit shown in figure 6. These findings were similar to those reported by Banti,<sup>9</sup> Dameshek and Schwartz<sup>20</sup> and Tigerit and Duncan<sup>2</sup> who injected dogs and guinea pigs with immune *hetero*-antibodies produced in other species.

FIG. 8—SPHEROCYTES IN SMEAR OF VENOUS BLOOD OF DO-POSITIVE RECIPIENT SEVEN DAYS AFTER TRANSFUSION OF ANTI DO PLASMA. 1500 X

#### DISCUSSION

The prolonged destruction of recipient dogs' Do-positive cells after injection of incompatible plasma is in striking contrast to the very rapid elimination of donated Do-positive corpuscles after transfusion to immunized Do-negative recipients. In the human species, recipients' cells are likewise known to be destroyed over long periods of time after transfusions of incompatible plasma or of blood from dangerous universal donors,<sup>32-34</sup> while incompatible donated cells often disappear with relative rapidity.<sup>3, 35, 36</sup> In neither species, however, is it entirely clear how the various destructive mechanisms operate under these circumstances.

With the evidence at hand it seems likely that the very rapid elimination of donated Do-positive cells is due in large measure to intravascular hemolysis, both by the direct action of complement on sensitized cells and by the traumatic effect\* of circulation on injured and agglutinated cells. Intravascular erythrophagocytosis probably plays a very minor role.

The concentration of hemoglobin in recipient dogs' plasma is usually maximal, or nearly so, within five to ten minutes after incompatible cells are injected, but the peak may not be reached until three to five hours have elapsed. Review of the experiments thus far completed shows that the maximal plasma hemoglobin mass, calculated on the basis of highest plasma hemoglobin concentration and estimated blood volume, is in each case equivalent to approximately 50 to 75 per cent of the hemoglobin contained in the transfused incompatible cells. In estimating the total amount of hemoglobin liberated intravascularly, however, one must also take into account (a) hemoglobin excreted in the urine or taken up by renal tubules or by other tissues prior to the moment at which maximal plasma hemoglobin concentration is reached, and (b) hemoglobin liberated intravascularly after the concentration in the plasma reaches its peak.

Data thus far obtained therefore indicate that well over 50 to 75 per cent of the cells that rapidly disappear from the recipient's circulation are destroyed intravascularly and that a relatively small proportion of the cells may be sequestered and destroyed extravascularly by the reticulo-endothelial system. This conjecture is based upon the assumption that hemoglobinemia is the result of intravascular hemolysis and that hemoglobin liberated from erythrocytes by reticulo-endothelial cells is converted to bilirubin before being released into the blood stream.<sup>2</sup> In any event, when anti-Do plasma is transfused, the relative importance of the several destructive mechanisms may be quite different from that encountered after injection of incompatible cells.

Experiments in progress<sup>36</sup> should demonstrate more precisely how dog erythrocytes are destroyed *in vivo* under a variety of conditions simulating those encountered clinically.

### SUMMARY

1. Dogs injected intravenously with dog erythrocytes containing one or more antigenic factors lacking in their own red cells developed iso-hemagglutinins and hemolysins exhibiting characteristics of immune antibodies.

2. Transfusions of incompatible whole dog blood and plasma were carried out under controlled conditions. Pretransfusion observations were made and followed by closely spaced post-transfusion measurements of serologic and hematologic alterations.

3. The rate of destruction of incompatible donated corpuscles was determined by tagging the cells with radioactive iron and also by employing the technique of differential agglutination of erythrocytes. It was thereby shown that all cells

\* Because of technical difficulties encountered in measuring mechanical factors in this aspect of the problem will be dealt with in a separate communication.

incompatible donated cells disappeared from the recipient's circulation within the first thirty to ninety minutes following transfusion. The probable mechanisms and relative importance of intra- and extravascular destruction of erythrocytes are briefly discussed.

4 Destruction of recipient dogs' corpuscles by donated immune plasma was relatively slow, and spherocytosis and increased osmotic fragility of the recipient's cells were evident for periods as long as twenty days. These observations are compared with those made in human beings after transfusions of plasma and of blood from dangerous universal donors.

5 The titer of complement in the sera of recipient dogs was sharply reduced for at least five hours after all transfusions of incompatible whole blood, but isoagglutinin titers were less regularly reduced after such transfusions.

6 Other notations of interest included estimates of the concentrations of serum bilirubin, sodium and potassium, determinations of clotting time, prothrombin concentration, and observations on red cell morphology, intravascular erythrophagocytosis, and shifts in distribution of leukocytes and in the electrophoretic patterns of plasma.

### CONCLUSION

The transfusion experiments thus far completed with dog blood are considered only exploratory. They are sufficient nevertheless to justify the conclusion that the iso-immune systems in the dog may be used to advantage in quantitative studies on certain hemolytic phenomena that cannot be satisfactorily investigated in human beings.

### ACKNOWLEDGMENTS

It is a pleasure to acknowledge the technical assistance of Mrs. Jane Peters, Miss Mary Jane Izzo and Miss Shirley Deshon.

# HEMOLYTIC REACTIONS PRODUCED IN DOGS BY TRANSFUSION OF INCOMPATIBLE DOG BLOOD AND PLASMA

## II RENAL ASPECTS FOLLOWING WHOLE BLOOD TRANSFUSIONS

By CHARLES L. YUILE, M.D., THEODORE F. VAN ZANDT, A.B., DONALD M. ERVIN, M.D., AND LAWRENCE E. YOUNG, M.D.

DEATH FROM renal insufficiency with the postmortem findings of hemoglobinuric or lower nephron nephrosis frequently follows acute hemolytic reactions of various etiology including the transfusion of incompatible blood<sup>1-3</sup>. Extensive studies based largely upon the injection of solutions of hemoglobin, related pigments or laked blood as substitutes for hemolysis *in vivo*, have been carried out over a period of many years, but have failed to explain the exact mechanism of this type of renal failure<sup>3-5</sup>.

The hemolytic reactions in dogs produced by transfusion of incompatible dog blood described in the preceding paper<sup>6</sup> afford an ideal opportunity to study the effects of such reactions upon the kidney under a variety of conditions simulating those seen clinically.

It has been shown by several groups of investigators, using different animal species, that induced hemoglobinemia within the range encountered in most acute hemolytic disturbances in human subjects, produces only transient changes in normal animals with previously undisturbed renal function<sup>4, 7-10</sup>. On the other hand, particularly if the urine is acid, the injection of hemoglobin into an animal in a severe state of dehydration<sup>11</sup> or with kidneys previously injured<sup>4</sup> results in the formation of pigment casts in the renal tubules followed frequently by death in uremia. Similar results have been reported in dogs following the injection of very large amounts of hemoglobin<sup>6</sup> or laked red blood cells<sup>1</sup>.

This preliminary report is concerned with a controlled study of renal function carried out in conjunction with the experiments described in the preceding paper. The results indicate that in the *normal* dog with *either acid or alkaline* urine a combination of the intravascular hemolysis and other profound changes resulting from the transfusion of incompatible blood is not sufficient to produce renal failure.

### METHODS

Procedures used in the immunization of recipient dogs and the collection and transfusion of incompatible blood have been described in part one of this report.<sup>6</sup> All dogs were normal mongrels vaccinated against distemper. Female animals were used in all experiments involving quantitative renal function studies, urine being obtained through a curved metal catheter. For male dogs a ureteral catheter was used. Water was given by stomach tube at intervals prior to each transfusion to insure adequate urine flow.

From the Departments of Pathology and Medicine, The University of Rochester School of Medicine and Dentistry, Rochester, N. Y.

The studies described in this report were conducted in part under a contract between The University of Rochester and the Office of Naval Research. This paper was presented in an abridged form at the International Hematology Congress, Buffalo, New York, August 26, 1948.

and sodium bicarbonate was added when alkaline urine was desired. In order to obtain the secretion of acid urine with a pH of about 6.0 or less at the time of transfusion dogs were fed a diet of horsemeat 200 Gm, lard 50 Gm and ammonium chloride 3 Gm for a period of three to four days.

Urinary hemoglobin concentration was determined by the cyanmethemoglobin method of Evelyn and Malloy.<sup>12</sup> Radioactive iron determinations<sup>14</sup> were made on the total hemoglobin excreted in those experiments in which the donated cells were labelled with this isotope.\*

Effective renal plasma flow was measured by means of *para* aminohippurate clearance (15)† Satisfactory blood and urine levels were obtained by injecting 0.5 to 0.8 ml of the drug intraperitoneally 15 minutes before each 20 minute collection period. Glomerular filtration rates were determined by measuring mannitol clearance (16)† in some experiments and creatinine clearance<sup>17</sup> in others.

TABLE 1—Summary of Fourteen Hemolytic Transfusion Reactions in Dogs in which Renal Functions were Studied

Dog number	Sex	Weight	Initial pH of urine	Blood transfused	Recipient's antibody titer	Maximal plasma Hb	Approx. period of hemoglobinuria	Total Hb excreted % of Hb transfused	Maximal blood urea nitrogen
		Kg		ml		mg per 100 ml	hours		mg per 100 ml

\* Quantitative studies of renal function carried out before during and after the transfusion reaction.

† The aeration method of Van Slyke and Cullen<sup>15</sup> was used to determine the concentrations of blood urea nitrogen.

### EXPERIMENTAL OBSERVATIONS

The renal aspects of hemolytic reactions produced by transfusion of incompatible whole blood were studied in fourteen transfusions given to 8 different dogs. Data of a general character relating to all experiments are summarized in table 1.

The results of single or multiple transfusions were essentially similar with as many as four reactions having been produced in the same animal at varying intervals.

\* Drs. James A. Bush, John W. Harden and Henry Teitelbaum assisted with the radioactive iron activity.

† Determinations of *para* aminohippurate and mannitol clearance were done by Dr. J. H. Cusson and Dr. Christine Watcher.

vals of at least two weeks. The urine at the time of transfusion was alkaline, with a pH of over 7.5, in eight experiments, and acid, pH 5.5 to 6.2, in five experiments. In one instance the pH of the urine was not determined since the reaction occurred unexpectedly after a transfusion of mismatched blood given for another purpose.

Transfusions ranged in size from 35 to 205 ml. of whole blood. When compared with individual dog weights this represented from 2.5 to 15 ml. per kilogram or the approximate equivalent of from 200 to 1000 ml. of blood transfused into a 70 kilogram human being.

The maximum plasma hemoglobin concentration after each transfusion was apparently related both to the amount of blood injected and to the initial antibody titer, the height of which appears to determine to some extent the rapidity of red cell destruction.

Hemoglobin invariably appeared in the bladder urine within five or ten minutes after completion of the transfusion. Exact measurements of the duration of hemoglobinuria were not possible in all experiments, but the shortest period observed was eight hours and none extended beyond twenty-four hours. The variations encountered were unrelated to the pH of the urine, but maximal plasma hemoglobin concentration and body weight were apparently contributing factors. The total amount of hemoglobin excreted by the kidneys ranged from 10 to 40 per cent of that in the transfused blood and came only from this source since in the five experiments involving donor red cells labelled with radio-active iron the isotope content of the total hemoglobin excreted by the recipient's kidneys was identical with that in an equivalent amount of hemoglobin from the donor.

The concentration of urea nitrogen in the blood was determined at daily intervals for periods up to one week after each transfusion. Maximal values obtained are listed in column 9. A transient elevation was noted in most instances usually at 24 hours. This was slightly more marked in the group with acid urine but in all there was a prompt return to the pretransfusion level in from 48 to 72 hours.

Slight proteinuria was noted for a few days after the cessation of hemoglobinuria in some but not all animals with both alkaline and acid urine. There was no consistent alteration in the specific gravity of the urine at any time. Catheterized specimens of urine collected during the period of hemoglobinuria all contained variable amounts of brown granular material while the urinary sediment of dogs with initially acid urine also showed moderate numbers of pigmented casts.

Quantitative studies of renal function were carried out before, during and after the transfusion reaction in six experiments marked with an asterisk in table 1. In each of these a similar, clearly defined pattern was observed with respect to the renal excretion of hemoglobin, the rate of effective renal plasma flow and the glomerular filtration rate. The findings in two characteristic experiments are illustrated in figure 1. It is to be noted that there were no essential differences between the two experiments, in one of which alkaline urine and in the other acid urine was initially being excreted. Plasma hemoglobin concentrations are shown in the top graph and hemoglobin excretion rates are plotted in the second graph. The latter curves are roughly parallel to those of hemoglobinemia down to the

threshold level, and the calculated renal clearances of the pigment are found to be essentially similar to those observed after hemoglobin injection<sup>10</sup>

Minor irregularities in the excretion rates of hemoglobin are related to the transient changes in effective renal plasma flow and glomerular filtration illustrated in the two lowest graphs of figure 1. The biphasic character of these curves

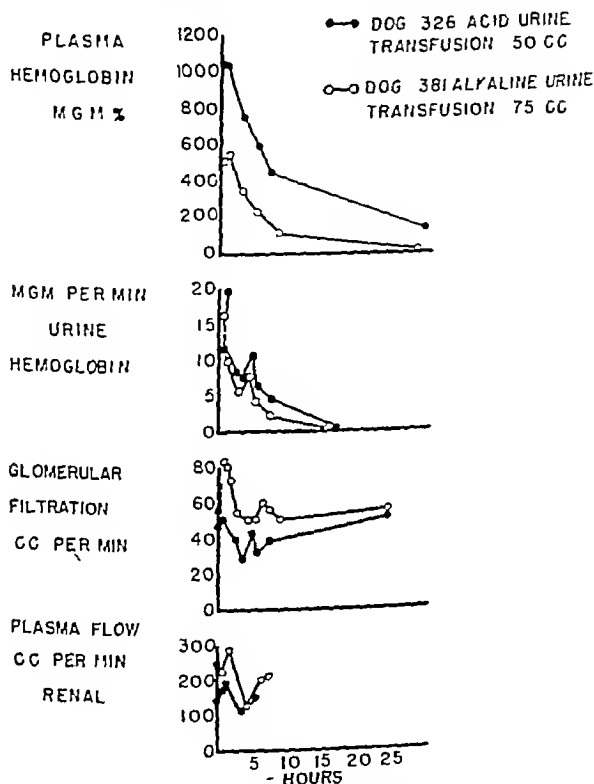

FIG 1—TRANSIENT CHANGES IN RENAL FUNCTION ASSOCIATED WITH HEMOGLOBINEMIA AND HEMOGLOBINURIA PRODUCED BY TRANSFUSION OF INCOMPATIBLE WHOLE BLOOD IN DOGS. Dog 326 Weight 13.5 kilo Antibody titer 1-64 Dog 381 Weight 10.0 kilo Antibody titer 1-16

was a constant finding, with an early rise and a secondary fall below the baseline after several hours. While the degree of these changes was somewhat variable from experiment to experiment, both functions had returned to normal in from six to twenty-four hours in all instances. These transient alterations in renal hemodynamics appear to reflect the general vascular response to a transfusion reaction and indicate that a specific renal vasoconstrictor action of hemoglobin demonstrated some years ago<sup>19, 20</sup> is not an important factor in the development of renal insufficiency.

All animals were well hydrated at the start of each experiment and no oliguria developed, although urine flow was usually reduced for short periods when plasma flow and filtration were at low levels.

Figure 2 illustrates, in two typical experiments, the finding of a temporary alkalinization of the urine during the period of hemoglobinuria which occurred following transfusion of incompatible blood in all animals with initially acid urine. The mechanism of this change is not yet clear but may represent a compensatory effort on the part of the kidney to prevent the accumulation of large amounts of precipitated hemoglobin in the renal tubules. Maximal pH readings coincided with the highest concentrations of hemoglobin in the urine, suggesting that some neutralization results merely from the addition of hemoglobin, which

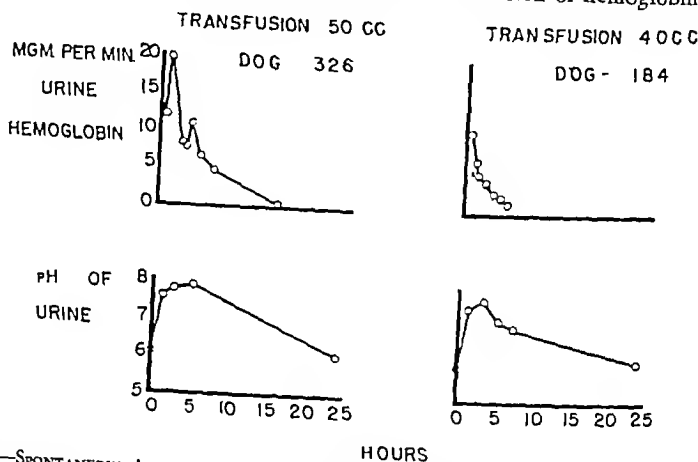

FIG 2—SPONTANEOUS ALKALINIZATION OF URINE DURING PERIOD OF HEMOGLOBINURIA INDUCED BY TRANSFUSION REACTIONS IN DOGS WITH INITIALLY ACID URINE AND NORMAL KIDNEY FUNCTION

has been observed *in vitro* but some interference with the excretion of acid by the lining cells of the distal convoluted tubules is also a possibility.

Two dogs, numbers 1309 and 1182, table 1, were killed twenty-four hours after transfusion reactions, similar to those after which the animals were followed throughout the recovery period. One other animal, 43-326, table 1, having apparently recovered from the transfusion reaction, died suddenly after forty-eight hours. Postmortem examination revealed an acute peritonitis which was attributed to contamination of the *para*-aminohippurate injected intraperitoneally. The kidneys of all three dogs were grossly normal. Histologically, the only finding of note was a small amount of brown, crystalline and granular pigment in occasional distal convoluted and collecting tubules in the two dogs with initially acid urine.

#### DISCUSSION

A critical analysis of the literature dealing with injection of hemoglobin solutions reveals that the mere production of levels of hemoglobinemia comparable

to those seen clinically in most acute hemolytic disorders has little or no damaging effect upon kidney structure or function in normal human subjects or animals

Flink<sup>3</sup> stressed the importance of degree of hemoglobinemia in the development of renal damage, being unable to produce renal injury in dogs unless the initial plasma hemoglobin concentration was 3.7 Gm per 100 ml or the average of the initial and the 24 hour plasma concentrations was 2.2 Gm per 100 ml. From the rather inadequate information available in the literature it is doubtful whether such concentrations ever occur following clinical transfusion reactions and the data presented in this and the preceding paper indicate clearly that the degree of maximal plasma hemoglobin concentration attained is not proportional to the amount of incompatible blood transfused. From the figures in table 1, the plasma concentrations which would have resulted from the sudden liberation of all the hemoglobin in the transfused blood can be calculated. In the experiments in which small transfusions were given the calculated and observed values correspond closely, whereas following larger transfusions the maximal plasma hemoglobin concentrations were only slightly higher than those following small transfusions. This indicates that the degree of hemoglobinemia induced was limited by the ability of the body to destroy incompatible cells. Dog 43-380 illustrates this point, since had all the transfused red blood cells been rapidly hemolyzed, the initial plasma hemoglobin concentration would have been 4.0 Gm per 100 ml instead of the observed concentration of 1.36 Gm per 100 ml.

Although it is obvious from the work of Flink and others that excessive degrees of hemoglobinemia, directly or indirectly, can produce disturbances of renal function, this alone is probably an uncommon cause of hemoglobinuric nephrosis in man. On the other hand there are innumerable clinical and experimental examples of renal insufficiency which have resulted from the association of a moderate grade of hemoglobinemia and some nephrotoxic process.<sup>1, 2, 4</sup> This latter factor can be characterized in some instances as the general or local effect of such agents as shock, ischemia, a chemical poison, infection, or dehydration. However in many acute hemolytic processes, notably those resulting in human subjects from the transfusion of incompatible blood, the cause of serious renal complications is not always clear. Since hemolysis during transfusion reactions is associated with profound changes of a generalized nature, it was considered possible that these might secondarily affect the kidney in a manner comparable to the more specific factors enumerated above. In the present study only normal dogs were used in order to determine whether the combination of these general effects with the concurrent hemoglobinemia was alone sufficient to produce renal insufficiency. Experimental conditions were varied with respect to size of transfusion, antibody titer of recipient, and hydrogen ion concentration of the urine. From the data presented it is apparent that within the range of these variables table 1 only minor, transient changes in renal function were observed. A comparison of the findings in dogs with initially acid urine and those with alkaline urine reveals that in the former, pigment casts occurred in the urine and persisted for 24-48 hours for at least forty-eight hours in the kidneys studied histologically.

that nitrogen retention was slightly more marked. The final outcome, however, was the same in both groups of animals.

Hemolytic transfusion reactions in dogs suffering from shock, anemia, dehydration, and other conditions simulating those for which transfusions are frequently given clinically are being studied at the present time.

### CONCLUSIONS

1. The normal dog's kidney reacts to the transfusion of incompatible dog blood in a manner similar to that observed after hemoglobin injection as far as the excretion of the pigment is concerned.

2. Lowering the pH of the urine to a level of 5.5 has no effect on the final outcome of the reaction nor on the mild, transient alterations in renal function which occur.

3. This type of hemolytic transfusion reaction, similar in most respects to that encountered in human subjects, does not of itself produce renal failure nor the pathological picture of hemoglobinuric or lower nephron nephrosis.

4. The findings in these experiments lend further support to the concept that the development of serious renal complications after a transfusion reaction results from a combination of the hemolytic process with some degree of previous or concomitant kidney damage related to the various clinical states for which transfusion therapy is indicated.

# EFFECTS OF THE INTRAMUSCULAR ADMINISTRATION OF BAL (2,3 DIMERCAPTOPROPANOL) IN A SUBJECT WITH THE SICKLE CELL TRAIT CASE REPORT

B<sub>3</sub> WILLIAM J KUHN, M D

A VARIETY of studies have indicated that the sickling phenomenon can be accelerated by a number of substances, when any one of the latter is mixed with the appropriate blood, these include carbon dioxide,<sup>1</sup> bacterial cultures, sulfhydryl compounds such as H<sub>2</sub>S, BAL (2,3 dimercaptopropanol), cysteine and glutathione,<sup>2</sup> sodium bisulfite and cevitamic acid.<sup>4</sup> However, there is no clear evidence that individuals harboring the sickle cell trait have ever developed sickle cell anemia, either spontaneously, or when exposed to agents which are known to accelerate sickling in vitro.

The sickle cell trait occurs in about 8 per cent of all Negroes in this country and is generally considered to be distinct from sickle cell anemia. The latter occurs in a much smaller proportion of the Negro population. The former condition is recognizable by observing the development of sickling in moist sealed preparations of freshly drawn blood. Sickle cell anemia is, in addition, associated with a variety of clinical manifestations: anemia, signs of increased blood destruction, abdominal pain, and other diverse effects, most of them related to an increased tendency to circulatory stasis and thrombosis.

The case to be described is one in which acceleration of sickling occurred in an individual harboring the sickle cell trait who was given BAL in oil intramuscularly. Exposure to this known accelerating compound failed to precipitate the picture of sickle cell anemia.

## CASE REPORT

The patient was a Negro female who entered another hospital on July 9, 1948, with complaints of sore throat, fever, headache and rash. The serologic test for syphilis was found to be strongly positive and she was therefore given penicillin and arsenic treatment for six days. Following this she was transferred to the Salt Lake General Hospital where intensive antiluetic treatment with penicillin, mapharsen and bismuth was initiated. On the seventh day of treatment she became disoriented and generally uncooperative. Because she was thought to have developed an arsenical encephalopathy with psychosis, arsenic was discontinued and the patient was given BAL (2,3 dimercaptopropanol) 100 mg in oil intramuscularly every four hours. At this time her temperature ranged from 102 to 103 F. The volume of packed red cells was 51 ml per 100 ml, reticulocytes were 0.5 per cent, the van den Bergh 1:2 mg per cent (indirect 1:1) and the sedimentation rate 3.

In the ensuing ten days she received a total of almost 5 grams of BAL. Shortly after BAL was discontinued the volume of packed red cells was found to be 34 ml and the reticulocyte count was normal. Thrombophlebitis developed at this time and in addition a consolidative process appeared in the lower part of the left lung which was compatible with a pulmonary infarct. The superficial femoral veins were ligated bilaterally. Her mental status remained poor. Serial lumbar punctures showed increases in spinal fluid protein up to 70 mg per cent. The plasma iron was 48 micrograms per 100 ml.

From the Department of Medicine, University of Utah, College of Medicine and the Salt Lake County General Hospital, Salt Lake City, Utah.

Ten days after the administration of BAL the reticulocyte count had increased to 10.4 per cent, the sedimentation rate was 35 ml, and the volume of packed red cells 23 ml. Repeated van den Bergh tests and urine indices remained the same as on the original examination. Clinically the patient showed no evidence of jaundice. White blood counts showed increases up to 20,000 and a shift to the left with a slight myelocytic and myeloblastic response. The differential smear showed red cells which were slightly macrocytic and myeloblastic response. The differential smear showed red cells which were slightly macrocytic and the blood indices were confirmatory. An ascending urinary tract infection developed which was associated with numerous leukocytes in the urine, elevated temperature and BUN, and cultures which were positive for coliform organisms. This was treated successfully with sulfadiazine over the next four weeks. Her impaired mental status persisted as did her anemia. The pulmonary process and thrombophlebitis showed gradual improvement. Reticulocyte counts increased to as high as 13 per cent following which they returned to normal. Urine and fecal urobilinogens yielded consistently normal values. Several previous twenty-four hour sickling preparations had all been negative. However it was later found that sickling preparations which stood for more than twenty-four hours yielded positive findings and it may be assumed that these would have been positive earlier had sufficient time been allowed. In view of the fact that sulphydryl compounds are known to accelerate sickling *in vitro*,<sup>2</sup> it was thought that the use of BAL in this patient may have produced an acceleration of sickling *in vivo* with subsequent thrombotic phenomena and anemia.

TABLE 1—Influence of BAL on Rate of Sickling

Date of Specimen	Percentage of sickled cell Number of hours following withdrawal of specimen						
	0	1	4	8	16	24	48
9/5/48 (prior to second course of BAL therapy)	0	0	0	0	0	0	5
10/4/48			Intramuscular BAL started				
10/7/48 (one hour following injection of 100 mg BAL in oil 1 ml)	0	1*		25*	90		

\* These examinations revealed abnormal type of rouleaux.

In order to ascertain the exact role played by this compound in the genesis of her anemia, it was decided to reinstitute BAL therapy in doses similar to those employed previously. Prior *in vitro* studies were performed with the patient's blood utilizing saturated aqueous BAL. These are described in detail in a subsequent section (see Observations). In brief they indicated that BAL increased the rate of sickling and the viscosity of the blood as judged by fresh BAL treated moist preparations and comparative sedimentation rates.

During the ten day period of BAL therapy there was no appreciable alteration in the volume of packed red blood cells which remained about 35 ml per 100 ml, nor was there any evidence of increased blood destruction. Consistently normal values were obtained for urine and fecal urobilinogen, reticulocyte count and serum bilirubin. It is of interest that in spite of this the rate of sickling was influenced considerably by the administration of BAL (see table 1). The rate of sickling was markedly accelerated one hour after the administration of BAL as compared with that in specimens of blood just prior to the injection of this drug. Corresponding with this it was observed that the erythrocyte sedimentation rate was markedly decreased after the administration of BAL, thus confirming *in vitro* results. The patient showed no evidence of thrombotic phenomena during the trial period with BAL. Her subsequent course has been good with the exception of her mental status which has remained somewhat clouded. Her blood picture has shown steady improvement and all hemolytic indices remained normal. The patient was recently discharged in good condition and with normal blood values.

#### OBSERVATIONS

Routine fresh sealed preparations indicated that the patient's red blood cells sickled slowly. No sickle cells were seen even after twenty-four hours. A third

six hours there was two per cent sickling and at seventy-two hours the majority of the red blood cells were sickled. The use of  $\text{CO}_2$  or  $\text{H}_2\text{S}$  gas bubbled directly through the blood accelerated the rate of sickling considerably, so that small numbers of red cells became sickled immediately and most were sickled at twenty-four hours. Saturated aqueous BAL acted similarly when one drop was mixed with an equal amount of the patient's blood and a fresh sealed preparation was made. It is interesting that following contact with sulfhydryl compounds many of the

FIG. 1.—THE IN VITRO EFFECT OF BAL (AQUEOUS) ON SEDIMENTATION RATE. (BAL-blood mixtures were prepared by adding one drop of saturated aqueous BAL to 5 cc of whole blood.)

FIG. 2.—EFFECT OF INTRAMUSCULAR INJECTION OF BAL ON SEDIMENTATION RATE IN SUBJECT WITH SICKLE CELL TRAIT

red blood cells appeared more limp and flabby, and rouleaux were of an abnormal type.

Comparative sedimentation rates carried out on the patient's blood with and without the addition of water soluble BAL indicated that the sedimentation rate of BAL treated blood was decreased more than five fold in comparison to untreated blood (see fig. 1). The mixture of BAL with the blood of normal persons, on the other hand, failed to alter the sedimentation rate. BAL-blood mixtures were prepared by adding one drop of saturated aqueous BAL to 5 ml of whole blood. Following institution of the second series of BAL injections, sealed preparations

were made one hour after administration of the drug. These were found to sickle considerably more rapidly than did the preparations made before the drug was given (see table 1). Serial sedimentation rates were found to increase and decrease alternately before and after an intramuscular injection of 100 mgm. of BAL in oil (see fig. 2).

### DISCUSSION

Study of the present case offers several points of interest. In the first place, it emphasizes the necessity for observations of fresh blood preparations over a period of several days when sickling is being sought. Routine 24 hour specimens showed no sickling in the present case whereas specimens observed at later intervals were definitely positive. This, of course, becomes of less importance as knowledge regarding the known accelerating substances accumulates. In the present case, for instance, it was possible to reduce the time of sickling materially by the use of sulfhydryl compounds. This is in conformity with the findings of Thomas and Stetson.<sup>2</sup>

It has been demonstrated, furthermore, that the intramuscular administration of BAL accelerates the rate of sickling. Winsor and Burch<sup>1</sup> obtained comparable effects when they utilized methods which increased the CO<sub>2</sub> concentration in patients with sickle cell disease.

The addition of aqueous BAL to specimens of the patient's blood resulted in retardation of the sedimentation rate, similar results were obtained following the intramuscular injection of BAL in oil. The value of the sedimentation rate in detecting sickling was first recognized by Winsor and Burch,<sup>1</sup> who found that the erythrocyte sedimentation rate of the blood of patients with sickle cell anemia could be slowed or accelerated by alternate saturation with carbon dioxide and oxygen. Inhalation of pure oxygen was found to accelerate the sedimentation rate, on the other hand, keeping a tourniquet on the arm for ten minutes retarded the sedimentation rate, as did also rebreathing into a paper bag. Normal blood was found to be affected only slightly by these gases.

The experiments of Thomas and Stetson have indicated that sulfhydryl compounds similarly retarded the sedimentation rate in individuals with sickle cell disease. Of special interest in the present case was the alteration in sedimentation rate following exposure of the patient to BAL. This occurred, however, in the absence of any of the pathognomonic criteria of sickle cell anemia.

The possible development of sickle cell disease in Negroes harboring the sickle cell trait is a question which has evoked some divergence of opinion. The trait is said by Bauer<sup>3</sup> to change occasionally to the disease under certain conditions of anoxemia and stress if a large number of red blood cells are caused to sickle. Such conditions would include local or general anoxemia resulting from infectious disease, surgical procedures, or other conditions known to slow the circulation of the blood, such as pregnancy and blood transfusion. On the other hand, Wintrobe<sup>4</sup> and Singer, et al.<sup>7</sup> insist that sickle cell trait and sickle cell disease are separate entities, and that carriers of the trait never acquire sickle cell disease. Singer and associates<sup>7</sup> studied the comparative survival rates in normal individuals of trans

fused cells from persons with the trait and with sickle cell anemia and found that the former survived as long as did normal red blood cells, whereas the latter survived a much shorter period of time. On the basis of these studies, they have suggested that sickle cell anemia develops because of an alteration in the red blood cell cytoskeleton which is qualitatively different from the structural anomaly responsible for the sickling phenomenon.

The etiology of the anemia in the present case was not definitely ascertained. Administration of BAL to the patient did not produce any evidence of hemolysis or any of the other characteristics of sickle cell disease. What role, if any, the compound played in relation to the anemic and thrombotic episodes earlier in her clinical course is difficult to determine. It is quite probable that administration of the drug was in no way involved. The manner in which her anemia developed, i.e., without any evidence of hemolysis and concomitant with thrombophlebitis and a consolidative pulmonary process, followed shortly thereafter by a severe renal infection, all suggest an anemia of infection rather than anemia due to blood loss, which is the only other possibility which comes to mind. The low plasma iron might have been found in either case but the absence of hypochromia and microcytosis of the red blood cells, and the lack of any clinical evidence or history of blood loss makes the former possibility the more probable.

#### SUMMARY

The effects of the intramuscular administration of BAL in a Negro harboring the sickle cell trait have been presented. It was observed that the rate of sickling was accelerated and the erythrocyte sedimentation rate was retarded in the presence of BAL both in vitro and apparently in vivo. However, the administration of BAL produced none of the pathologic sequelae characteristic of sickle cell disease.

#### ACKNOWLEDGMENT

I wish to thank Dr. M. M. Wintrobe, Professor and Head of the Department of Medicine, University of Utah College of Medicine for his numerous invaluable suggestions and criticisms.

## RH ISOSENSITIZATION IN THE AMERICAN NEGRO

By MILTON S. SACKS, M.D., JOSHUA A. COHEN, M.D., and J. F. BERRY, M.D., of the Baltimore Rh Laboratory

THE INCIDENCE of Rh isosensitization in the American Negro has been studied by numerous investigators. However, no comprehensive studies on the occurrence of Rh isosensitization have been published. As a result of the paucity of such data, there has been a more or less general impression that Rh isosensitization is less prevalent in the American Negro than in the white population. The purpose of this paper is to report on the basis of a statistically significant series of Negro patients treated in this laboratory.

The material for this study was taken from the files of the Baltimore Rh Laboratory for the period beginning August 1, 1954, and ending November 30, 1955. During this period a total of 55,561 individuals have been studied. The majority of Rh negative individuals are routinely examined for antibodies by testing a small pooled, O MN Rh positive erythrocytes suspended in 30 per cent bovine albumin solution. The specificity of any antibody found is likewise determined. The plan of prenatal study as carried out in this laboratory has been previously published.

### RESULTS OF STUDY

In the group of 55,561 patients there were 43 (15 Caucasoid individuals of whom 8,889 (17.48 per cent) were Rh<sub>0</sub> negative. The remainder, 11,196 were American Negroes of whom 1,302 (8.37 per cent) are Rh<sub>0</sub> negative. The incidence of Rh negative individuals, particularly in the Caucasoid group, is somewhat higher than previously established figures since many such patients, when found to be Rh negative elsewhere, have been referred to us for study. Excluding this factor, the patients constituting this study represent a completely unselected and random group. In the group of 8,889 Rh<sub>0</sub> negative Caucasoid individuals 503 instances of Rh isosensitization were encountered. Among these cases were 34 patients who have been studied through two pregnancies and 9 instances of sensitization by transfusion in males. Correction for these factors leaves a total of 460 isosensitized Caucasoid females. The incidence of isosensitization is, therefore, 5.2 per cent.

Among the 1,302 Rh<sub>0</sub> negative Negro patients 77 instances of Rh isosensitization were encountered. Thirteen of these patients have also been observed through two pregnancies. Thus, the corrected figure of 64 sensitized individuals represents an incidence of isosensitization in the Negro group of 4.9 per cent. The difference in the incidence of isosensitization between the Caucasoid and Negro group was found to be insignificant on statistical analysis.\*

## CLINICAL ASPECTS

Examination of the clinical records of this group of patients demonstrated a significant fact which may be one of the reasons for the existing general impression concerning the rarity of erythroblastosis fetalis among the American Negroes. In contrast to the Caucasoid group, approximately one half of the infants were inadequately studied during the neonatal period. These patients were hospitalized in many different institutions throughout the city. Thus many relatively mild cases of erythroblastosis fetalis were undoubtedly over-looked. In spite of this fact, 14 cases of clinically obvious hemolytic disease of the newborn were encountered in the series. Of the latter group 4 were severe enough to lead to death. As will be observed in table 1 the degree of isosensitization observed in 64 cases is entirely comparable to that seen in Caucasoid individuals. Yet, the immediate mortality rate of 6.2 per cent is distinctly lower than the overall mortality from congenital hemolytic disease. Whether this is actually representative of the true situation, or whether this is simply another evidence of inadequate clinical follow-up, cannot be accurately stated at this time.

Two illustrative examples of erythroblastosis fetalis in the American Negro will be cited.

*Case 1.* H. S., a 43-year-old Negro, para 7 with 6 living children, was first seen in the last trimester of her pregnancy. The past history was negative for previous blood transfusions and erythroblastosis fetalis. She was found to belong to type O MN Rh negative. Serologic studies revealed a nonvalent antibody in titer of 3 units with serum-suspended cells, and 6 units with albumin-suspended cells. The blocking test was negative. Antibody specificity was Rh<sub>0</sub>. Serologic studies were carried out every two weeks, and a significant rise in titer was observed. On her last visit, two weeks before delivery, the antibody titer with serum-suspended cells was found to be 48 units while the titer with albumin-suspended cells was 384 units. The blocking test was now strongly positive. She delivered an infant weighing

$$\sigma_D = \sqrt{\frac{p^1 q^1}{n_1} + \frac{p^2 q^2}{n}}$$

where

p = per cent of nonsensitized cases  
q = per cent of sensitized cases

and

n = total number of cases

$$\sigma_D = \sqrt{\frac{0.94825 \times 0.5175}{8,889} + \frac{0.95084 \times 0.04916}{1,302}}$$

$$\sigma_D = 0.65\%$$

$$\text{Difference (D)} = 5.175\% - 4.916\% = 0.26\%$$

$$\frac{\sigma}{\sigma_D} = \frac{0.26}{0.65} = 0.4$$

so that difference is not statistically significant

3335 grams whose blood type was O MN Rh. The initial hemoglobin level was 15 grams and there were 22 per cent nucleated red blood cells in the peripheral blood. Jaundice appeared two hours after birth and lasted three days. Hepatomegaly and splenomegaly were also present. The infant received no transfusions and was discharged from the hospital apparently clinically normal on the fifth postpartum day. On the twentieth postpartum day examination in the Pediatric Clinic revealed the liver and spleen to be barely palpable. There was no jaundice but blood study revealed a hemoglobin of 4.0 grams. Multiple transfusions of fresh type O MN Rh negative blood were given with subsequent uneventful recovery.

*Case 2.* S. A. 20-year-old Negro para 2, with 2 living children was first seen in the thirty-second week of her pregnancy. The past history revealed no instance of previous blood transfusions nor of any previous erythroblastic infants. The patient's blood type was found to be O MN rh, that of her husband O MN Rh, Rh<sub>1</sub> (probable genotype R<sup>1</sup> R<sup>1</sup>). Both previous children were O MN Rh, rh (genotype R<sup>1</sup> r). Initial serologic studies revealed univalent antibodies in a titer of 96 units with albumin suspended cells. The blocking test was negative. Antibody specificity was Rh<sub>0</sub>. Blood studies at biweekly intervals demonstrated practically no rise in the antibody titer. On the day prior to delivery serologic study revealed a titer of 196 units with albumin-suspended cells and only 2 units with serum suspended cells. There were no agglutinins active in saline solution and the blocking test was negative. The patient was delivered of an infant weighing 3285 grams whose blood type was O MN Rh<sub>1</sub>. The initial hemoglobin

TABLE 1—Antibody Titers in Various Cell Suspension Media in 64 Isosensitized Negro Women

Units of antibody	Suspension media			Blocking test
	Physiologic saline solution	Pooled human serum	30% bovine albumin solution	
0	42 cases	10	0	Positive 30 cases
1-10	28 cases	37	9	Negative 34 cases
10-100	4 cases	17	24	
100-1000	0 cases	0	15	
1,000-10,000	0 cases	0	6	

\* Ten cases not studied with this medium

was 15 grams and blood smears showed 4 per cent nucleated red cells. Because of a falling hemoglobin a 90 cc. transfusion of fresh O MN Rh negative blood was given to the infant on the second day of life. Severe jaundice was observed on the second day associated with hepato-splenomegaly. Despite transfusions every other day the hemoglobin continued to drop. During the next forty-six days numerous small transfusions were necessary to maintain a satisfactory hemoglobin level. In all a total of 620 cc. of blood was given over the forty-six day period.

These cases, which are presented to illustrate the severity of erythroblastosis fetalis in Negro infants, by no means illustrate ideal methods of management. It is rather interesting to observe that Case 1 illustrates a variety of erythroblastosis fetalis not infrequently encountered in which the development of marked anemia occurred three to four weeks after delivery in an infant apparently clinically normal, during the early neo-natal period. In view of the current procedure of early discharge of postpartum patients, this variety of erythroblastosis fetalis is undoubtedly overlooked unless special attention is paid to blood studies during the first four to six weeks of life.

Since the incidence of the Rh-negative type in the American Negro (8.4 per cent) is only somewhat more than one half of that in Caucasians (13 to 15 per cent) the actual number of cases of erythroblastosis fetalis in Negroes will be correspondingly lower. Nevertheless, survey of a large series has revealed that there is no significant

difference in the incidence of isosensitization of Rh<sub>0</sub>-negative individuals in either group Rh isosensitization and erythroblastosis fetalis may be expected to occur in the American Negro in direct proportion to the incidence of the Rh-negative type in that race. Similar observations have been made in other races.<sup>3</sup>

#### SUMMARY

1. Studies of the Rh factor in 11,486 pregnant female American Negroes revealed 1,302 who were Rh<sub>0</sub> negative (8.4 per cent). Sixty-four cases of isosensitization were encountered which gave an incidence of 4.9 per cent in the Rh-negative patients. In comparison, among 8,889 Rh<sub>0</sub>-negative Caucasians, 460 cases of isosensitization (5.2 per cent) were encountered. The difference was found to be statistically insignificant.

2. Two typical examples of erythroblastosis fetalis in American Negro infants are presented.

# THE PATHOGENESIS OF ERYTHROBLASTOSIS FETALIS

By B S KLINE, M D

**M**ICROSCOPIC examination of numerous sections of the placenta of an 8½ month pregnancy in a case of erythroblastosis fetalis, in which the baby lived 33 minutes, and of the placenta of a 7½ month pregnancy in a similar case in which the baby lived 25 minutes, showed occlusion of peripheral blood vessels of many villi and trunks by agglutinated red blood cells and fibrin. Associated with the vascular thromboses, there were, in places, necrosis of the walls and of regional tissues with rupture and hemorrhage of fetal blood, containing numerous intact nucleated red blood cells, into regional intervillous spaces. Through the broken surfaces, adjacent maternal blood was in contact with the fetal circulation.

These observations indicate the mechanism of transfer to the mother of incomparable fetal red blood cells in cases of erythroblastosis fetalis and of the transfer to the fetus of the maternal antibody that produces the anemia.

The two placentas showed, in addition to hemorrhages that apparently occurred at or very shortly before the time of expulsion, others somewhat older with abundant fibrin and red blood cells, some with degenerating nuclei, covering the ruptured surfaces of villi and trunks, indicating that the intermingling of fetal and maternal bloods had been stopped by the clotting of fetal blood at the sites of hemorrhage.

Vascular thromboses with necrosis and rupture of peripheral tissues of many villi and trunks and hemorrhage of fetal blood into regional intervillous spaces was observed in the placenta of all 13 additional cases of erythroblastosis fetalis and of all 213 cases in the last half of normal pregnancy examined and reported previously.<sup>1</sup> Although the changes in the 213 placentas of the last half of normal pregnancy observed microscopically are the same as those in the two cases of erythroblastosis fetalis described above, it is doubtful if the fetal hemorrhages into intervillous spaces would have been recognized as such, without the previous identification of unquestionable fetal hemorrhages with nucleated red blood cells into intervillous spaces in the two placentas here reported.

Since the first report, by Levine and Stetson<sup>2</sup> of transplacental transfer of an immunizing blood factor inherited from the father various explanations of the mechanism concerned have been offered.

The permeability of the placenta of mammals has been found to increase progressively to the end of pregnancy as the layers of tissue between maternal sinuses and fetal circulation diminish (Flexner and Gellhorn<sup>3</sup>). Levine<sup>4</sup> has assumed that the thinning of the placental barrier and the pressure in the fetal circulation, greater than in the local maternal sinuses, afford ample opportunity for the escape into the sinuses of a minute number of fetal red blood cells in one or another form.

Haldane<sup>5</sup> is of the opinion that the abnormal permeability of the placenta

From the Laboratory Department Mt. Sinai Hospital Cleveland, Ohio

to the passage of an antigen from the fetus to the mother is at least often genetically determined. Burnham<sup>6</sup> has suggested that subclinical deficiency of vitamin C in the mother might be sufficient to permit a break in the integrity of the capillaries of the chorion with escape of Rh positive fetal blood, thus leading to isoimmunization of the Rh negative mother. Naeslund and Aren<sup>7</sup> have recently reported a case of toxemia of pregnancy in which the full term placenta showed multiple gross hematomas and microscopically in these areas, gaps in the epithelium of villi and in the walls of their blood vessels. The photomicrographs show

FIG. 1.—Placenta #1979 of 8½ month pregnancy. Case of erythroblastosis fetalis (Magnification about 300 X) (Right middle area) Occlusion of blood vessel of villus by agglutinated red blood cells and fibrin. Necrosis of walls and of regional tissues with rupture.

marked vascular engorgement suggesting that the regional fetal hemorrhage was due to rupture following obstruction to the return of venous blood at or very shortly before the expulsion of the placenta.

Javert<sup>8</sup> has reported the finding of gross hematomas in the placenta of 8 of 34 cases of erythroblastosis neonatorum and in 7 of 10 examined microscopically, nucleated fetal red blood cells were found.

The observations especially in the two cases reported here and also in all the additional 13 cases of erythroblastosis fetalis and in all the 213 cases in the last half of normal pregnancy studied, indicate that hemorrhage of fetal blood from many villi and trunks into the regional intervillous spaces occurs in the last half of all pregnancies as a result of occlusion of the involved peripheral blood

FIG 2.—Placenta #2243 of 7½ month pregnancy Case of erythroblastosis fetalis (Magnification about 150 X ) (Middle lower area ) Very recent hemorrhage from villus into regional intervillous spaces (Many of the fetal red blood cells are nucleated )

FIG 3.—Placenta #2243 (Magnification about 200 X ) (Center) Recent hemorrhage from villus into regional intervillous spaces showing early formation and molding of clots (Some of the fetal red blood cells are nucleated )

FIG 4—Placenta #1979 (Magnification about  $300\times$ ) (Left and upper) Recent clot containing numerous intact and degenerating nucleated fetal red blood cells (especially upper right) following hemorrhage from villus (Reprinted by permission of the American Journal of Obstetrics and Gynecology)

FIG 5—Placenta #1979 (Magnification about  $350\times$ ) (Center and right.) Clot containing intact and degenerating nucleated fetal red blood cells following hemorrhage from villus

FIG 6—Placenta #1979 (Magnification about  $200\times$ ) (Left lower and center right upper) Fetal hemorrhage from peripheral vessels of trunk with recent blood clot formation

FIG 7—Placenta #2330 of a 9 month pregnancy Case of erythroblastosis foetalis (Magnification about  $400\times$ ) Villi with double epithelial lining and thick stroma

vessels by agglutinated red blood cells and fibrin and necrosis and rupture of the walls and of the regional fetal tissues<sup>1</sup> It is possible that the primary damage is due to the excretion of waste products of metabolism

The placenta in every one of the 228 cases reported showed, in addition to recent fetal hemorrhages, older ones with the clots composed mostly of fibrin stained by hemoglobin of laked fetal red blood cells, and degenerating and degenerated fetal red blood cells Fetal blood clots, apparently still older, consisting of little more than fibrin are the most conspicuous finding in all placentas after mid-pregnancy The oldest clots were observed in various stages of organization

In the placenta of 8 of the 15 cases of erythroblastosis fetalis, the villi showed the changes characteristic of the disease They were much thicker than normal and some were edematous The surface epithelium was thickened and in places double The stroma was thicker than average and compact where not edematous Many of the central vessels of villi and trunks showed degenerative changes and shrinkage, in places complete obliteration Some showed thickened endothelium and prominent perivascular fibrosis

The villi of erythroblastosis fetalis, with thick double epithelial covering and thick stroma, resembled those of the first few months of normal pregnancy The thickening and the doubling of the epithelial covering, the thickening of the stroma and the other changes may well have been a response to their constant exposure to the harmful fetal red blood cell antibody of the maternal blood

Since it is now known that the erythroblastosis is a secondary manifestation, the designation *erythroblastosis fetalis* for the disease, is by no means satisfactory and appears to be no longer justified Furthermore, since it has been found that destruction of the incompatible fetal red blood cells in the disorder may occur in part by phagocytosis (references given in a previous article<sup>1</sup>), the term *hemolytic disease of the newborn* is not entirely accurate A more fundamental designation in keeping with the author's concepts would be "transplacental erythrocytotoxic anemia

#### SUMMARY

The mechanism of transfer, in cases of erythroblastosis fetalis, of incompatible fetal red blood cells to the mother and of maternal blood with antibody to the fetus, was observed especially well in 2 cases in which the infants were born alive

The two placentas showed occlusion of peripheral blood vessels of many villi and trunks by agglutinated red blood cells and fibrin Associated with the vascular thromboses, there were, in places, necrosis of the walls and of regional tissues with rupture and hemorrhage of fetal blood, containing numerous intact nucleated red blood cells, into regional intervillous spaces Through the broken surfaces, adjacent maternal blood was in contact with the fetal circulation

A more accurate designation for erythroblastosis fetalis would be "transplacental erythrocytotoxic anemia

# CORRELATION BETWEEN THE MEAN CORPUSCULAR VOLUME AND RETICULOCYTOSIS IN PHENYLHYDRAZINE ANEMIA IN SWINE

By F DOUGLAS LAWRASON, LT (JG), MCR, USNR, D C ELTZHOLTZ, CPHM, USN, C R SIPE, CPHM, USN, AND P K SCHORA, CPHM, USN

ONE OF THE causes of an increase in mean corpuscular size is a pronounced reticulocytosis.<sup>10</sup> The increase in the volume of the red blood cells due to this cause is usually a temporary finding which follows a sudden loss of blood, a hemolytic crisis, or any reaction which acutely stimulates the hematopoietic system. During treatment of pernicious anemia with specific therapy, it is not unusual to find in conjunction with the reticulocyte response a transient increase in the degree of macrocytosis as measured by the mean corpuscular volume.

When a macrocytic blood picture is associated with a reticulocytosis, it is often difficult to evaluate to what extent the larger size of the reticulocyte contributes to the mean corpuscular volume. This problem was encountered in the interpretation of hematologic data gathered during previous studies with swine at the Naval Medical Research Institute, Bethesda, Maryland. The present investigation was undertaken to study the correlation between the increased percentage of reticulocytes produced by phenylhydrazine hydrochloride and the mean corpuscular volume in swine under controlled conditions.

Phenylhydrazine has been used by numerous workers to produce both experimental anemia and reticulocytosis.<sup>1-7</sup> This drug and its derivatives have been considered hemolytic agents.<sup>8-9</sup> However, Goodman and Gilman<sup>10</sup> do not consider the chemical action of the drug hemolytic in nature. They believe the drug enters the red cell, splits part of the hemoglobin to hemin and denatured globin, and the hemin, acting as a catalyst, changes the remaining hemoglobin to methemoglobin and possibly other unidentified substances. Phenylhydrazine usually does not cause depression of the bone marrow and probably does not affect the immature red cell<sup>11</sup> or the white cell.<sup>12</sup> Erythroid and myeloid hyperplasia have been noted in bone marrow of animals treated with the drug.<sup>1-12-17</sup>

## MATERIALS AND METHODS

Six adult swine averaging 185 pounds in weight were used for these studies. They were procured from a hybrid stock predominantly Duroc Jersey with an admixture of Poland-China and Chester White. All six swine were kept in a common pen measuring approximately 10 by 20 feet. Their diet as recommended by the U S Department of Agriculture consisted of a 17 per cent protein-vitamin mineral mixture and 83 per cent whole yellow corn. Brucella abortus agglutination tests were negative.

Animals were bled in the fasting state. The blood was obtained from the deeply lying jugular veins in the lower neck. The bone marrow was aspirated from the sternum with a Turkel needle and approximately 0.1 to 0.2 cc. of marrow blood was withdrawn. The preparation of the smear-imprint was made immediately upon aspiration. All other laboratory determinations were carried out by standard methods.

The same amount of phenylhydrazine hydrochloride was given to all of the animals on each day of treatment. The drug was given orally with a handful of food for the first nine doses. Beginning with the tenth dose and continuing to the end of the study it was given intravenously in a 2 per cent aqueous solution into the same plexus of veins from which the animal was bled.

### RESULTS

Initially all 6 swine were considered hematologically normal with an average erythrocyte count of 6.9 million per cu. mm. (fig. 1). The average mean corpuscular

FIG. 1.—Course of the average red blood count, reticulocyte count, and mean corpuscular volume in the five adult swine administered phenylhydrazine hydrochloride. The amount of phenylhydrazine HCl and time of administration is shown at the top of the graph.

volume (MCV) of the red cells for the group was 60 cubic microns and the reticulocyte count was 0.3 per cent. Phenylhydrazine hydrochloride was fed by mouth in daily doses of 0.2 to 0.4 Gm. for the first nine days. The dose was increased to 0.5 Gm. on the tenth day and was given intravenously (fig. 1). Little or no immediate reaction was noted with the administration of 0.5 Gm.; however, when 1.0 Gm. was given intravenously the animals exhibited mild to moderate weakness following injection. This reaction lasted from one to three minutes. On the forty-second dose the drug was increased to 2.0 Gm. and the weakness following the injection became more severe and lasted five to ten minutes. The severe response observed with the higher dose may have been due to the fact that when it was administered, all animals were severely anemic, listless, and weak. On the fortieth day the drug was discontinued.

One animal, number 5, failed to respond with a reticulocytosis. It became rapidly leukopenic and severely anemic and died from intercurrent infection on the fourteenth day, after receiving only 4.4 Gm of phenylhydrazine. At autopsy the bone marrow exhibited an extreme hypoplasia of both erythroid and myeloid components. Since the response of this pig diverged widely from the rest of the group

FIG. 2.—Relation of mean corpuscular volume to per cent reticulocytes in five swine treated with phenylhydrazine hydrochloride

and from the usual response to this drug, the data gathered from this animal were not included with the data of the group

The total dose given to the 5 remaining animals ranged from 0.30 to 0.35 Gm per kilogram of body weight, or approximately 28 Gm. Of these 5 pigs, 3 died between the thirty-ninth and fiftieth day and the remaining 2 survived and recovered. The total dose received by each of the 2 surviving animals was 30.7 Gm. One animal was found to be pregnant toward the end of the experiment. Incomplete abortion occurred two days before death of the animal. During the last ten

days of the study all of the animals developed sterile abscesses at the sites of injection

Figure 1 demonstrates the course of the average red blood count (RBC) for the group of 5 swine. The RBC of 2 of the animals dropped below one million shortly before death but the lowest average level for the entire group was 1.6 million. It will be noted that the average reticulocyte count for the 5 animals was maintained above 50 per cent for one month, and over 90 per cent for sixteen days. During ten days of this latter period, 3 of the animals maintained a reticulocytosis of approximately 100 per cent. The hemoglobin and hematocrit decreased proportionately to the RBC but are not shown on the graph. At the time when the reticulocytosis was marked and when numerous Heinz-Ehrlich bodies were seen, the spectrophotometric determinations of the hemoglobin may have given falsely high readings because of the peculiar turbidity of the solution. A similar turbidity has been described for *in vivo* and *in vitro* studies with phenylhydrazine and has been considered to be due to the release of the Heinz-Ehrlich bodies from the erythrocytes.<sup>11</sup>

The average MCV closely followed the trend of the reticulocytosis and both reached a maximum simultaneously. The maximum MCV of the group average was 133 cubic microns (fig. 1). The MCV of one of the surviving animals which had maintained a reticulocytosis close to 100 per cent for ten days remained at 140 cubic microns during this period. In figure 2 the MCV is plotted with relation to the reticulocyte per cent for all determinations made in the five swine during the study. The regression line for this correlation is a straight line fitted to the data by the method of least squares. In determining this regression line, only the data up to 80 per cent reticulocytes were included. It can be seen that with each increment of 10 per cent in the reticulocytes the MCV increases 6.8 cubic microns plus or minus a standard deviation of 7.8 cubic microns. The reason for using the selected data will be discussed.

The bone marrow of all animals was studied periodically. Beginning at the eleventh to twentieth day and continuing throughout the time of administration of the drug, the bone marrows of the 5 swine exhibited marked erythrocytic hyperplasia (figs. 3a, 3b, 3c, 3d). The myeloid-erythroid ratio was reversed. From 25 to 75 erythroblasts were encountered for every immature white cell. Many of the erythroblasts were quite immature and commonly found in large aggregates containing many pronormoblasts and basophilic normoblasts. Frequent multinucleated erythroblasts were seen (fig. 3a). Mitoses occurred in every stage of maturation and unusual numbers were seen occurring in large nests of erythroid regeneration. A normal pig bone marrow is shown for comparison in figure 3e. The myeloid series did not appear to be disturbed. The peripheral leukocyte counts were erratic throughout the experiment but at no time did they reach leukopenic levels in any of the five animals. Most of the swine developed a leukocytosis terminally which was probably, for the most part, a reaction to terminal infection.

#### DISCUSSION

Clinically, a delayed reaction to phenylhydrazine, manifested by a progressive anemia sometimes occurring many days after discontinuation of the drug, is well

known<sup>18, 19</sup> Experimentally, the effect of the drug upon the red cells seems to occur with little delay. Upon discontinuance of the drug, recovery from the anemia promptly occurs.<sup>20</sup> In the 2 surviving swine no delayed effect of the drug on the RBC was observed.

There is some uncertainty as to whether the action of phenylhydrazine is hemolytic in character<sup>10</sup> or is due to the aplastic effect of the benzol ring as some investigators believe.<sup>9, 16</sup> At any rate, animal number 5 reacted as if it were poisoned with benzol. The pig developed a marked leukopenia and progressive anemia within the first week and died on the fourteenth day of treatment. At autopsy an extensive hypoplasia of all elements in the bone marrow was found. The other 5 swine exhibited the usual response to phenylhydrazine. The variation in response observed in the one animal can not be explained.

The much discussed Heinz-Ehrlich bodies were seen in peripheral blood and for the most part appeared to be within the adult erythrocytes. Cruz<sup>11</sup> considers this fact, among other evidence, to support the theory that phenylhydrazine attacks only the adult and not the immature cell. He believes that these refractile bodies are evidence of destruction within the red cell. No observations were made in this study on whether or not phenylhydrazine attacks only the adult erythrocyte. However, in view of the extreme erythroid hyperplasia in the bone marrow and the high reticulocytosis in the peripheral blood during intravenous administration of the drug, it would appear that the drug did not attack the immature red cell.

The data used for the calculation of the regression line seen in figure 2 were those occurring below the 80 per cent reticulocyte level. Above this level a more extensive scattering of points and apparent lack of continued close linear correlation occurred. During this period of observation the animals were extremely ill, severely anemic, and 3 of the 5 died. The 2 surviving pigs appeared moribund when the drug was discontinued. Wintrobe<sup>20</sup> has pointed out that in pernicious anemia a close correlation exists between the erythrocyte count and the MCV of the red cells when the anemia is moderate, but when the anemia is extreme a close correlation is not found. Similarly, in these swine, the correlation between the number of reticulocytes and the MCV probably was affected by the severity of the anemia.

Qualitatively the bone marrow during this period did not appear to be as hyperplastic as it did earlier in the experiment. Even though the majority of the red cells in the peripheral blood were reticulocytes, it does not seem likely that the erythroid regeneration in the bone marrow could have been proceeding at an ideal maximum rate since the general metabolism was undoubtedly severely disturbed. It may be that at the higher dose of phenylhydrazine practically all of the adult erythrocytes were destroyed thus leaving only reticulocytes in the peripheral blood. Therefore, at the near 100 per cent level the reticulocyte response is probably only an apparent maximum and not a true index of optimum erythrocytic regeneration.

However, in spite of the wide scattering of values between the 80 and 100 per cent reticulocyte level, it appears that the majority of the points tend to cluster toward MCV values lower than expected. The reason for this is not entirely clear. If the animals were iron deficient during this period of observation the smaller mean corpuscular volume of the red cells may possibly be explained. Experiment 1

anemia produced by phenylhydrazine usually is not considered to be complicated by an iron deficiency since the iron from the destroyed cells is returned to the system for new hemoglobin formation. However, sterile abscesses developed at the site of injection of the drug in all of the swine. Robschey-Robbins and Whipple<sup>21</sup> and others<sup>22-23</sup> have shown that in the presence of a chronic inflammatory reaction, such as a sterile abscess, the rate of production of new hemoglobin diminishes because iron is diverted to the tissues and is not made available for hemoglobin synthesis. Therefore, toward the end of the experiment the anemia may have become an iron deficiency anemia.

Another explanation is based upon the previously discussed possibility that the bone marrow was less active during the period when the majority of circulating cells were reticulocytes. Thus, the relative percentage of nearly mature, and therefore smaller, reticulocytes would increase. This trend, if pronounced, may have become sufficient to account in part for the apparent shift of the previously linear correlation. In the final analysis, it is likely that many factors affected the correlation in this high range of reticulocytosis.

Below a reticulocytosis of 80 per cent, a close correlation between the per cent of reticulocytes and the mean corpuscular volume was found. However, since there is a large variation in individual determinations as evidenced by the standard deviation of 7.8 cubic microns, it would be difficult to attribute a macrocytosis to an associated reticulocytosis if the reticulocytes were not increased beyond 10 per cent. Nevertheless, from the data it is possible to determine approximately the role a moderate reticulocytosis would play in the increased mean corpuscular volume found in a macrocytic blood picture in swine.

#### SUMMARY AND CONCLUSIONS

1. Six adult swine were given phenylhydrazine hydrochloride orally and intravenously. Hematologic observations, which included periodic bone marrow studies were made before, during, and after the administration of the drug.

2. Five swine responded to the drug in the usual manner with progressive anemia, reticulocytosis, and erythrocytic hyperplasia of the bone marrow. Three animals died between the thirty-ninth and fiftieth day of the experiment after receiving a total dose of 0.30 to 0.35 Gm. per kilogram of body weight. Two swine survived and recovered after receiving a similar dose.

3. One animal died on the fourteenth day of the experiment and exhibited a course which closely resembled that of benzol poisoning. Rapid and progressive granulocytopenia, anemia, and extreme universal hypoplasia of the bone marrow were observed.

4. A direct correlation between the mean corpuscular volume of the red cell and the per cent reticulocytes was found within the limits of 0 to 80 per cent reticulocytosis. With each increment of 10 per cent in the reticulocytes the mean corpuscular volume increased approximately 6.8 cubic microns.

# FETAL AND ADULT HEMOGLOBINS IN THE BLOOD OF INFANTS AFFECTED WITH HEMOLYTIC DISEASE OF THE NEWBORN

By ERIC PONDER, M D , D Sc , AND PHILIP LEVINE, M D

A CONSEQUENCE of a preferential hemolysis of red cells containing fetal Hb by the Rh agglutinin-lysin system (Jonxis<sup>6</sup>) should be an increase in the proportion of adult Hb in the blood of infants affected with hemolytic disease, and this proportion should be even greater if, as Jonxis believes, the affected infant develops adult Hb in utero as a protective mechanism. As pointed out by Baar,<sup>1</sup> the conclusions of Jonxis are in contradiction with the results of Baar and Hickmans and of Baar and Lloyd<sup>2</sup>; these results were obtained, however, before the relation of the Rh factor to hemolytic disease of the newborn was appreciated. An independent determination of the proportions of fetal and adult Hb in the bloods of normal newborn infants and of infants affected with hemolytic disease of the newborn may therefore throw light on the situation.

The proportion of fetal and of adult Hb in a mixture of the two can be determined by methods which measure the rate of denaturation of Hb by alkali, the human fetal type denaturing slowly and the adult type rapidly. The method of Brinkman, Wildschut, and Wittermans<sup>3</sup> and that of Brinkman and Jonxis<sup>4</sup> require special apparatus, and Baar and Lloyd's<sup>2</sup> simpler modification of Horowitz's spectrophotometric method requires a photometer more sensitive than that usually available. A procedure which makes the determination of the amount of alkali-resistant Hb much less dependent on the sensitivity of the photometer involves the precipitation of denatured alkaline globin-hematin with half-saturated ammonium sulfate at the isoelectric point.

## METHOD

Red cells are obtained from cord blood, washed, and hemolyzed by freezing and thawing. Sufficient water is added to make a 10 Gm./100 ml. solution of hemoglobin. A volume of 0.2 ml. is added to each of five beakers, each containing 10 ml. of NaOH-glycine buffer of pH 12.15 at 26°C. (4 vols. 7.5% glycine plus 5.85% NaCl per liter and 6 vols. of 0.1 N NaOH). After 10, 20, 40, 60, and 80 minutes, 10 ml. of saturated ammonium sulfate containing enough N HCl to neutralize 10 ml. of the NaOH-glycine buffer is added to each mixture in succession. The alkali-globin-hematin precipitates are removed without delay by filtration with suction (filtering speed at least 10 ml./min.) and the five concentrations of Hb remaining are found either colorimetrically or photometrically as a percentage of the initial Hb concentration. A photometer such as the Lumetron is quite sensitive enough. The logarithms of the concentrations of Hb are plotted against time, except for the point corresponding to the shortest time; they usually fall on a straight line which, when extrapolated to zero time, gives the percentage of fetal Hb present in the mixture.

This method has been tested in two ways:

1. The percentages F of fetal Hb found by the method as applied to normal cord blood have been compared with those found by Baar and Lloyd's photometric method, in which the percentage of denatured Hb present in a mixture at any time is computed from the extinction coefficient of the mixture and the extinction coefficients of Hb and of alkali-globin-hematin. The logarithms of these percentages

From the Nassau Hospital, Mineola, N. Y., and the Rh Blood Testing Laboratory, Ortho Research Foundation, Raritan, N. J.

when plotted against time again fall on a straight line when the times are greater than about 10 minutes and the extrapolation of this line to zero time gives the percentage of fetal Hb originally present in the mixture. Table 1 shows the slope  $d(\log F)/dt$  of this line in 4 cases together with the slope of the line obtained by the method in which the denatured protein is precipitated at pH 7. It also shows the values of  $F_0$ , the percentages of fetal Hb present and found from the intercepts of the lines on the log F axis.

The largest discrepancies between the results of the two methods is usually associated with the values of F for 10 minutes the Baar and Lloyd method tending to give higher values. This point and points for shorter times however are not included in the drawing of the straight line since they lie on a curve which turns upward from it the points corresponding to longer times usually lie very well

TABLE 1

	Precipitation at pH		Baar and Lloyd's method.	
	$d(\log F)/dt$	$F_0$ per cent	$d(\log F)/dt$	$F_0$ per cent
1	0.0036	87	0.0044	88
2	0.0038	85	0.0035	88
3	0.0036	70	0.0046	75
4	0.0048	87	0.0044	94

TABLE 2

	1 vol. with F = 81 A = 19 plus			
	0.2 vol. A = 100	0.5 vol. A = 100	1 vol. A = 100	2 vol. A = 100
Calculated				
Found	67.5 67	54.0 51	40.5 44	27.0 25
	1 vol. with F = 72 A = 28 plus			
	0.2 vol. A = 100	0.5 vol. A = 100	1 vol. A = 100	2 vol. A = 100
Calculated				
Found	60.0 64	48.0 50	36.0 35	24.0 21

on the line irrespective of the method used to obtain them. Since both are extrapolation methods an agreement to within  $\pm 5$  per cent in the final value of F can be considered satisfactory.

2. In several experiments one volume of cord blood containing F per cent of fetal Hb and A per cent of adult Hb was mixed with 0.2, 0.5, 1, and 2 volumes of blood containing adult Hb only (A = 100 per cent). The method was then tested by using it to find the percentage of fetal Hb present in the mixture. Table 2 illustrates the extent of the agreement between the values found and those calculated and shows that the method is applicable over a wide range of concentration of fetal Hb.

## RESULTS

The proportions of fetal and of adult Hb were found by this method in the cord blood of 15 normal full-term infants and of 15 infants affected with hemolytic disease of the newborn. The red cells of the affected infants were coated in the case of the newborn. The reaction with Coombs' serum varying from + to +++++. In the instance of normals the average percentage of fetal Hb was 75 with a standard

deviation of  $\pm 3.9$ , in the group of affected infants, the average percentage of fetal Hb was 78.6, with a standard deviation of  $\pm 4.1$ . There being no significant difference in the percentage of fetal Hb in the two groups, nothing to support Jonxis' conclusions was found.\*

#### SUMMARY

A method is described by means of which the rapidly denatured adult Hb can be separated from the slowly denatured fetal Hb by denaturing with alkali and precipitating the denatured material at its isoelectric point. When applied to 15 normal cord bloods and to the cord bloods of 15 infants affected with hemolytic disease of the newborn, the method showed no significant difference in the percentage of fetal Hb present.

\*Determinations of the quantity of fetal Hb have also been carried out at pH 12.7 and no significant difference has been found between the average values for 7 normal cord bloods and the cord bloods of 7 infants affected with hemolytic disease.

# THE COINCIDENCE OF MEDITERRANEAN ANEMIA AND PERNICIOUS ANEMIA IN A YOUNG SICILIAN

By WILLIAM H. CROSBY (MAJOR, MC, AUS) AND HARRY J. SACKS  
(CAPTAIN, MC, AUS)

**P**ERNICIOUS anemia is ordinarily a disease of the middle years and old age. In individuals under 30 years of age, it is uncommon but not remarkable.<sup>1</sup> Mediterranean anemia particularly in its mild forms (target-oval-cell trait or thalassemia minor) is fairly common, occurring in about 6 to 8 per cent of all Italians studied.<sup>2</sup> The simultaneous occurrence of both pernicious anemia and Mediterranean anemia in one person has not previously been described. We report this association in one case, in which opportunity for careful studies of the blood and bone-marrow was afforded.

## CASE HISTORY

The patient, an enlisted man on duty at a fire station was born at Houston, Texas, July 19, 1920 of Sicilian parents. Family history was negative for blood diseases. The patient's mother died in childbirth while he was a boy. His father, one brother and one sister were known to have diabetes mellitus. One brother was killed in action in World War II. Four other siblings are living and well. The patient had the usual childhood diseases and except for minor illness had been well before the onset of his anemia.

The patient enlisted in the Army Air Forces in September 1946. In December 1946 he developed a severe and intractable diarrhea after eating the fruit of a cactus plant. This persisted with six to twelve watery stools per day for a month. Toward the end of this bout he felt weak, easily fatigued and breathless on moderate exertion. When he fainted on two occasions he went to his dispensary. On January 30, 1947 he was hospitalized at the Station Hospital, Fort Worth Army Air Field.

Physical examination on admission to that hospital showed a patient with a pallid skin, a yellowish tinge and pale mucous membranes. The tongue was very smooth. No other abnormalities were elicited. Blood pressure 110/70.

Laboratory work was reported as follows: RBC 3.0 million, hemoglobin 10.5 Gm, color index 1.0. The blood smear demonstrated macrocytes and tailed erythrocytes. The leukocyte count was 5700. Except for a shift to the right in neutrophils, the differential count was normal. Gastric analysis showed no free hydrochloric acid. The feces were negative for blood and parasites. Urinalysis and serologic test for syphilis were negative. Therapy with liver extract was begun on February 14. Reticulocyte count on February 21 was 3.5 per cent. Polychromasia was noted. On March 3 the blood picture was as follows: RBC 4.0 million, hemoglobin 14 Gm. There were many macrocytes and tailed erythrocytes. Some erythrocytes had basophilic stippling. The blood platelets were 495,000, the WBC 8,800. Liver extract was discontinued on March 5.

The patient was transferred to Brooke General Hospital on March 11. Physical examination on admission was unchanged from that reported earlier. The patient seemed pallid and listless. He was slender with dark complexion, hazel eyes and a sprinkling of gray hairs. There was no evidence of morbilli line to his gums. There was no remarkable lymphadenopathy; the liver and spleen were not palpable. Neurologic examination was negative. The blood counts were essentially unchanged from that of March 3. The patient was group O, Rh negative. There were no sickle cells. Hypertonic fragility was slightly decreased, 0.40-0.31. The blood serum was negative for cold agglutinins. Feces were repeatedly negative for blood, parasites and excessive fat. Gastric analysis with histamine was repeatedly negative for free hydrochloric acid. Urinary urobilinogen was 3.25 mg. per 24 hours. Indirect van den Bergh was 1.0-1.5.

From the Medical and Laboratory Services, Brooke General Hospital, Fort Sam Houston, Texas.

per 100 cc. X-ray of the chest and gastrointestinal system was negative. Proctoscopic examination on April 10 was negative.

A gastroscopy performed on April 22 revealed no evidence of atrophic gastritis\*. A bone marrow examination on April 12 showed no megaloblasts but on May 14 a few megaloblasts were noted with a slight increase in the number of immature erythropoietic elements present.

A short course of liver therapy was given in the attempt to elicit a reticulocyte response. At this time the patient was not anemic. Target cells were first noted in the peripheral blood; however, the patient was returned to duty and examined biweekly as an outpatient. The red cell count at this time was 4.8 million, the hemoglobin 14.7 Gm.

In mid August the patient's red count had fallen and he was readmitted to the hospital. At this time his tongue was sore. There were no neurologic signs or symptoms. The patient complained of easy fatigue and occasional indigestion with belching. Physical examination was unchanged from that of his first admission. The blood picture at this time was: RBC 3.38 million, hemoglobin 13.5 Gm, hematocrit 34 VPC, MCH 40, MCV 101, MCHC 39.7, reticulocytes 0.1 per cent, WBC 4,200, differential normal, platelets 380,000. Anisocytosis and poikilocytosis were evident. Gastric juice contained no free hydrochloric acid after histamine. Urinary urobilinogen 14.1 mg. per 24 hours. Icterus index 8. Indirect van den Bergh 1.4 mg. per 100 cc. Total serum protein 7.0 grams per cent, A/G ratio 2.2. Liver function tests, including cephalin flocculation, thymol turbidity, prothrombin time and bromsulfalein excretion were normal.

A study of aspirated bone marrow at this time revealed erythroblastic hyperplasia. The erythropoietic series consisted chiefly of megaloblastic cells in all stages of maturation; a few cells of the normoblastic series were present. The granulocyte series showed a normal maturation process except for the presence of occasional large hypersegmented neutrophils.

Just before treatment was begun a moderate splenomegaly was noted. The patient was now started on liver extract. There was a well-defined reticulocyte response with a peak level of 20 per cent. The red count rose rapidly from approximately 3.0 to approximately 5.0 million. As the poikilocytosis of pernicious anemia disappeared from the peripheral blood, the target-oval-cell trait became very evident. The patient was discharged from the hospital and from the Army on December 10, 1947.

## DISCUSSION

*Pernicious anemia.* Until this patient was studied the second time we were reluctant to make a diagnosis of pernicious anemia. It was suggested that the macrocytic anemia might have been nutritional following protracted severe diarrhea. This was ruled out by the fact of his relapse while on an adequate diet. The spruelike syndromes were ruled out by a normal small-bowel pattern on x-ray examination and by normal serum calcium and normal fecal fat.

There were many points raised against pernicious anemia. None eliminated the diagnosis but their very number cast suspicion on it. The patient was 26 years old. Pernicious anemia is classed with the degenerative diseases and is seen in the age bracket of arteriosclerosis, cancer and diabetes. Wintrobe<sup>3</sup> reports that of 319 cases of pernicious anemia admitted to Johns Hopkins Hospital from 1925 to 1940, only 4 patients were less than 30 years old.

Our patient was of Sicilian origin. In a study based on admissions to Peter Bent Brigham Hospital, Friedlander<sup>4</sup> reports that 0.16 per cent of all Italians were diagnosed pernicious anemia. The rate for Scandinavians in this same series was 7½ times as great (1.2 per cent), for the English, 5½ times (0.88 per cent).

The gastroscopic examination was negative in our patient. A normal appearing

\* Dr. Don W. Chapman of Baylor University, a member of the civilian professional staff of Brook General Hospital.

gastric mucosa is reported to be found in about 40 per cent of patients with pernicious anemia. Some of those who show atrophy will improve with liver therapy.<sup>6</sup>

It was noted further that in June our patient had been three months without treatment, yet had a normal erythrocyte count. Many cases of pernicious anemia will relapse in this time but some have gone as long as two years without treatment before they relapsed.<sup>6</sup>

There was absence of neurologic changes. vibratory and position sense were intact, there was no paresthesia. Pernicious anemia need not be accompanied by such changes. One of four clinical types of the disease, as classified by Dameshek, is a purely hematologic type, characterized by severe macrocytic anemia and by little if any neurologic involvement.<sup>7</sup>

The target cells found in the peripheral blood could only be explained by supposing there were two diseases. Adding this unlikelihood to the others discussed above we thought it best to make no definite diagnosis.

When the patient returned in relapse, the clinical picture of pernicious anemia was inescapable. There was a macrocytic anemia which responded with reticulocytosis and an increased total red cell count. The bone marrow demonstrated megaloblasts and hypersegmented polymorphonuclear neutrophils. There was absolute achlorhydria after histamine. There was evidence of increased hemoglobin dissolution manifested by a mild acholuric jaundice and increased urinary urobilinogen excretion in the absence of liver disease. There was inflammation and atrophy of the tongue. Lacking only was evidence of central nervous system involvement.

*Mediterranean anemia* When the mask of pernicious anemia with its large and distorted red cells was removed, the target-oval-cell trait became very evident. Mediterranean anemia occurs in degrees of severity varying from the fatal disease which is Cooley's anemia to the target-oval-cell trait, so benign that it cannot be called a disease.<sup>8</sup> The anemia is hereditary, following a mendelian pattern. Its severe form occurs in children whose parents both have a milder form of the disease. The mechanics of transmission have recently been well discussed by Daland and Strauss.<sup>9</sup>

It is of interest that with the simultaneous occurrence of these two diseases, the picture of pernicious anemia dominated. In patients observed with pernicious anemia occurring simultaneously with chronic blood loss the picture was hypochromic.

Our patient returned to Brooke General Hospital for a follow-up examination in February 1948. His blood picture was as follows: RBC 5.88 million, hemoglobin 16.5 Gm, hematocrit 47 VPC, MCH 28, MCV 80, MCHC 35. Cells on stained spreads were slightly hypochromic. The patient was examined at this time by Dr. William Dameshek of Boston who pointed out that hypochromic polycythemia is characteristic of mild Mediterranean anemia. Dr. Dameshek suggested, however, that this diagnosis be confirmed by examination of other members of the patient's family. This was done.

For most of the material we are indebted to the Medical Service of the Veterans Administration in Houston, Texas, which made blood counts and sent blood smears to us for examination.

The patient's wife age 41 Group O Rh positive Irish extraction She was negative for the target oval-cell trait

S B (father of patient) age 63 Diabetic Group A Rh negative RBC 4.35 million hemoglobin 13 Gm Target-oval-cell trait positive

M B N (sister of patient) age 38 RBC 4.53 million hemoglobin 12.5 Gm Target-oval-cell trait negative

J L B (brother of patient) age 33 Diabetic Group A Rh positive RBC 4.39 million hemoglobin 13.5 Gm Target-oval-cell trait positive

J B (brother of patient) age 28 RBC 5.37 million hemoglobin 15 Gm Target-oval-cell trait positive

F B (brother of patient) age 44 Group A Rh positive RBC 4.74 million hemoglobin 14 Gm Target-oval-cell trait negative

M B C (sister of patient) age 20 Severe diabetic Group O Rh positive RBC 4.67 million hemoglobin 14 Gm Target-oval-cell trait negative

P B (daughter of patient) age 3 Group O Rh positive Target-oval-cell trait positive

One maternal uncle and his daughter were negative for target-oval-cell trait

When last examined in March 1948 the patient was in good health. His red cell count was 6.0 million, his blood showed a high proportion of oval cells but only an occasional target cell was observed. When re-examined in November 1948, the patient's physical condition and blood counts were unchanged. He has continued to receive liver injections two to four times monthly.

#### SUMMARY

1. Coincidental Mediterranean anemia and pernicious anemia were found in a 26 year old soldier of Sicilian parentage.

2. The diagnosis of pernicious anemia was made on the finding of achlorhydria after histamine glossitis, megaloblastic bone marrow and macrocytic anemia which responded to liver extract on two occasions.

3. The diagnosis of mild Mediterranean anemia was made by finding the target oval-cell trait in the patient and in five members of his family.

4. It is of interest that target cells were not found in the peripheral blood until treatment with liver was begun. While pernicious anemia dominated, the character of the peripheral blood picture was macrocytic. Liver therapy corrected this, whereupon hypochromic polycythemia characteristic of mild Mediterranean anemia was found.

### INHERITANCE PATTERNS IN MEDITERRANEAN ANEMIA AND SICKLE CELL ANEMIA

IT HAS been amply demonstrated in recent years that the severest form of Mediterranean anemia known as Cooley's anemia, occurs in certain children, both of whose parents show mild forms of the disease<sup>1, 2</sup>

These mild forms are transmitted by either parent in a mendelian dominant fashion and such individuals with the mild target cell or leptocytic disease may be said to be heterozygous for the condition. On the other hand, cases of the severe disease appear to be homozygous for the hereditary trait. The marriage of two heterozygous individuals results (at least theoretically and in accordance with mendelian laws of inheritance) in 50 per cent severe cases, 25 per cent mild or heterozygous and 25 per cent without any evidence of the disease.

Mediterranean anemia and sickle cell anemia show many points of similarity.<sup>3</sup> Both conditions occur primarily in special racial groups, target cells and increased resistance to hypotonic salt solutions are common to both, the anemia does not respond to either the use of iron or splenectomy. Cases of sickle cell anemia have furthermore been described in individuals of Italian and Greek origin<sup>1, 4</sup> and cases of apparently typical Mediterranean anemia are occasionally found in Negroes.<sup>4</sup> As we have previously stated it is possible that both disorders may represent variants of a single larger hereditary abnormality characterized by an abnormal hemoglobin metabolism and defective, unusually thin red cells.

If the heredity of Mediterranean anemia is by now well known, that of sickle cell anemia has, at least until recently, eluded investigation. In line with the inheritance pattern in the former disease, it seemed possible that severe sickle cell anemia might be due to the inheritance of the sickle cell trait from both parents.<sup>2, 5</sup>

The trait itself has been shown to be inherited as a simple mendelian dominant and it seemed likely, therefore, as Neel<sup>6</sup> recently stated, that there existed in Negro populations a gene which in heterozygous condition results in sicklemia and in homozygous condition in sickle cell anemia.

Previous studies of the parents of patients with sickle cell disease had revealed no definite pattern of heredity in fact, in most instances only an occasional parent was found to have the sickle cell trait. On the other hand Neel who tested 42 parents of 29 patients with sickle cell anemia, found that every parent tested to date has sickled.

Neel placed especial reliance for the sickle cell test on a combination of the techniques described by Scriver and Waugh and by Hansen-Pruss. A tourniquet was applied to the finger for three to five minutes and then a drop of static blood from the finger was placed on a slide containing a small amount of Janus green or methylene blue. The preparation was then covered with a coverslip which was sealed with vaseline and examined at intervals up to seventy-two hours. Five preparations were routinely made. It was felt that the variable results obtained

by other observers might be explained in terms of lack of familiarity with the technics necessary to elicit sickling

This important observation will of course require confirmation from other sources before it can receive complete acceptance. However, the results by this experienced geneticist are so clear cut and at the same time so logical that negative results by other workers will, from now on, require considerable scrutiny. That the sicklers are heterozygous and the cases of sickle cell anemia homozygous explains much that has hitherto remained obscure. Nevertheless, the reason for red cell sickling and the exact difference between the red cells of the sickle cell trait and those of sickle cell anemia remain as mysterious as ever.

## HEMORRHAGIC DISEASE

TUBERCULOSIS AND STREPTOMYCIN R Dibre H E Brissaud and J P Soulier From the D-partment of Streptomycinotherapy, La Clinique Medicale des Enfants Paris France Sang 29 353-357 1949

Six cases of purpura were observed during one year The patients were treated for tuberculous meningitis or miliary tuberculosis with daily doses of streptomycin varying between 1 and 3 Gm Three purpuras were thrombocytopenic with diffuse hemorrhages Three were athrombocytopenic The relationship between tuberculosis and purpura is discussed In 3 cases the tuberculosis was in an acute phase in 3 others the tuberculosis was no longer progressive

The relationship between streptomycinotherapy and purpura was studied In 3 cases the streptomycin could not be concerned since the treatment had been discontinued eight five and two months before onset of purpura In the 3 other cases cure of the purpura was produced with blood transfusions In 1 case no relapse occurred when streptomycin was restarted In the 2 other cases recovery was complete without having stopped streptomycin Thus there was no apparent relationship between streptomycinotherapy and the mentioned purpuras

J.P.S

THROMBOCYTOPENIC PURPURA IN TUBERCULOSIS OF THE SPLEEN R Lapp (Medical Clinic of the University of Lausanne) Schweiz med Wschr 78 980 81 1948

The author describes 4 cases in which tuberculosis of the spleen was followed by thrombopenia Increased number of megakaryocytes are found in the bone marrow Splenectomy is recommended with protective streptomycin therapy

C.M

RESISTANCE OF THE BLOOD CLOT IN HEMOPHILIA J Král From the 1st Medical Clinic, Charles University Prague Cas lék čes 87 401 1948

Resistance of the blood clot is undoubtedly one of the best diagnostic signs in hemophilia being very low and even equal to zero in this disease In 2 patients suffering from hemophilia the author obtained a definite rise of the zero resistance by injecting 2 cc of rabbit serum This rise continued for several hours after the injection and was accompanied by an increase of red blood cells and blood platelets In both hemophilia and by a reduction of the clotting time The subcutaneous injection of the rabbit serum did not seem to convey any factor lacking in the hemophilic blood it probably developed some unknown mechanism affecting the resistance of the blood clot

M.L.N

PSEUDOHEMOPHILIA OR CHRONIC THROMBASTHENIA C W McLaughlin Jr From the Department of Surgery University of Nebraska Medical College Omaha Nebraska Arch Surg 51 635-645 1947

Two cases classified as pseudohemophilia are reported and the syndrome is compared with hemophilia (von Willebrand 1926) and chronic hereditary hemorrhagic thrombasthenia (Glanzmann 1926)

are discussed. The various means of controlling hemorrhage in pseudohemophilia are mentioned. In pseudohemophilia the bleeding tendency is said to become less marked with advancing years. Surgical treatment is contraindicated unless absolutely required.

**CAPILLARY FRAGILITY STUDIES (GÖTHLIN TEST) ON ONE HUNDRED PATIENTS RECEIVING DICUMAROL.** R. A. Jubelirer and H. I. Glueck. From the Department of Internal Medicine, The Jewish Hospital, Cincinnati, Ohio. *J. Lab. & Clin. Med.* 34: 448-457, 1949.

One hundred patients receiving dicumarol were studied to determine if any correlation existed between the occurrence of hemorrhage and increased capillary fragility as measured by the Göthlin test. Six of these patients had received dicumarol continuously; the shortest period was three months and the longest, nineteen months. None of these patients demonstrated a positive Göthlin test. Hemorrhage was observed seven times in 100 patients receiving dicumarol. In none of these was the Göthlin index positive. Seven patients demonstrated a positive Göthlin test and gave no clinical evidence of hemorrhage. G.E.C.

**EFFECT OF VITAMIN P LIKE SUBSTANCES ON CAPILLARY RESISTANCE IN THROMBOCYTOPENIC PURPURA IN RATS.** L. O. Randal and E. L. Stirlinghaus. From the Pharmacology Department, Hoffmann-La Roche Inc., Nutley, New Jersey. *Arch. Biochem.* 22: 132-138, 1949.

The decrease in capillary resistance produced by antiplatelet serum as measured by a skin suction test in rats was found to be prevented in part by flavonoid materials and also by certain hydroxy substituted compounds and quinones not obviously related to vitamin P. The test was therefore not specific for vitamin P like materials. Rutin was found much less effective per weight of dose than certain other materials with vitamin P activity. Ascorbic acid and  $\alpha$ -tocopherol phosphate were inactive in preventing the fall in capillary resistance produced by antiplatelet serum.

**EFFECTIVENESS OF DICUMAROL PROPHYLAXIS AGAINST THROMBOEMBOLIC COMPLICATIONS FOLLOWING MAJOR SURGERY. A FOUR YEAR SURVEY, 3304 CASES.** W. D. Wise, F. F. Loker and C. E. Bamber. From the Department of Surgery and the Department of Clinical Biochemistry, Mercy Hospital and the University of Maryland School of Medicine, Baltimore, Maryland. *Surg., Gynec. & Obst.* 88: 486-494, 1949.

This study of a large series of patients following major abdominal or pelvic surgery adds to the rapidly accumulating data demonstrating a statistically significant reduction in the incidence of postoperative thromboembolic complications with prophylactic anticoagulant therapy in those groups of patients in which the expected incidence is high.

The authors discuss the advantages of chemoprophylaxis over venous ligation, the advantages realized by a conservative rather than drastic reduction of prothrombin activity, and the necessity for rigid standardization of laboratory procedures.

## LEUKOCYTE MORPHOLOGY AND PHYSIOLOGY

(Studies of Blood Cells with the Phase Microscope Using the Shadow Method for Normal and Leukemic Cells.) **ETUDE SUR LES CELLULES SANGUINES AU MICROSCOPE A CONTRASTE DE PHASE ET PAR LA METHODE DE L'OMBRAOE (AVEC UNE ETUDE PARTICULIERE DES MEGAKARYOCYTES).** M. Bessis. *Rev. Hemat.* 4: 294-349, 1949. **ETUDE SUR L'ETALEMENT DES LEUCOCYTES DU SANG HUMAIN AU MICROSCOPE A CONTRASTE DE PHASE ET PAR LA METHODE DE L'OMBRAOE.** M. Bessis and M. Brila. *Rev. Hemat.* 4: 350-363, 1949. **ETUDE SUR LES CELLULES DES LEUCEMIES ET DES MYELOMES AU MICROSCOPE A CONTRASTE DE PHASE ET PAR LA METHODE DE L'OMBRAOE (AVEC UNE ETUDE PARTICULIERE DES CORPS DE AVEZ ET DE LA FORMATION DE CELLULES DE RIEDER).** M. Bessis. *Rev. Hemat.* 4: 364-395, 1949.

An exhaustive study of blood cells is made with the phase microscope illustrated by 176 microphotographs.

Successively the erythrocytes, the granulocytes, the lymphocytes, the thrombocytes and the megakaryocytes are studied. The structure of the megakaryocytes and thrombocytes seems to be identical.

thus confirming the relationship between these cells. The technic and the interpretation of the preparations are discussed. The normal polynuclears spread out well on plexiglass form but leukemic granulocytes do not spread as well. Polynuclears seen in severe infections spread out especially well on these artificial areas.

The structure of the spread out polynuclear is studied with the electron microscope. It appears identical to that described for the halo-plasm of thrombocytes.

In leukemic cells Auer corpuscles are very easily detected. In one case they were so numerous that it was possible to separate them by mechanical destruction of the cells.

The cells of myeloid and lymphoid leukemias and of myelomas are successively studied.

**INFRA RED SPECTROSCOPY WITH THE REFLECTING MICROSCOPE IN PHYSICS, CHEMISTRY AND BIOLOGY** R. Barr, A. R. H. Cole and H. W. Thompson. From the Department of Human Anatomy, Oxford, and the Physical Chemical Laboratory, Oxford, England. *Nature* London 163: 198, 1949.

The development of a reflecting microscope by Burch has widened the whole field of microscopy. An important extension of its use to include infra red spectroscopy is now reported. Among the examples given of the application of this technic is the spectrum of a crystal of anti-pernicious anemia factor isolated by Lester Smith. As a whole the spectrum did not show the general features of a polyamide. If it eventually proves to be so, the spectrum must be masked by other parts of the molecular structure. Another line of work which may prove of great hematologic interest is the study of infra-red spectral absorption of biologic cells. There seems every reason to hope that still greater powers of resolution may be obtained with further development of reflecting microscopes so that individual parts of cells may be studied.

S C

**THE HYPERSEGMENTATION OF NEUTROPHIL LEUKOCYTES** J. Kadry. From the Institute of General and Experimental Pathology and the 3rd Medical Department, Masaryk University, Brno, Československo 602 00.

Among 1000 cases of pathologic individuals 48 had hypersegmentation of neutrophils in their blood smears. Besides the commonly known occurrence of these cells in pernicious anemia and other diseases mentioned in the literature, the author calls attention to their very frequent presence in gastric neoplasms. After splenectomy, a considerable hypersegmentation appeared as a temporary phenomenon which disappeared after a certain time.

M. N.

**TRANSPORTATION OF THE ANAPHYLACTOGENIC PROPERTY BY EOSINOPHILS** Z. Z. Godlowski. From the Departments of Pathology and Pharmacology, Edinburgh University, Edinburgh, Scotland. *Brit J Exper Path* 29: 511-524, 1949.

Hypereosinophilia of a local or general character is the most constant feature in allergic conditions and therefore the eosinophil may play an important role in antigen-antibody interaction. Eosinophils were recovered from guinea pigs after an anaphylactic peritonitis had been produced by the injection of horse serum and egg white. The dosage of antigen was estimated from total protein nitrogen values. Various sera, eosinophilic and leukocytic antigens were tested for activity on sensitized guinea pig uterus (Schultz-Dale Test). Evidence has been presented to support the contention that the contraction of the sensitized uterus was precipitated by a specific agent carried by the eosinophil. Other leukocytes do not have this property. The author suggested that eosinophils may transport the antigen to the site of interaction between antigen and antibody.

O P I

**VARIATIONS IN WHITE BLOOD CELLS FOLLOWING THE ORAL ADMINISTRATION OF GLUCOSE TO DIABETIC AND NONDIABETIC** J. W. Jailer, D. T. Marks and P. A. Marks. From the Departments of Medicine, Anatomy and Obstetrics and Gynecology, College of Physicians and Surgeons, Columbia University, and the Presbyterian Hospital, New York, N. Y. *J Clin Endocrinol* 10: 1074-1080, 1950.

The administration of 100 Gm. of glucose in the form of a glucose tolerance test was given to 10

following patients 14 nondiabetics 15 diabetics 1 with Addison's disease 1 with Cushing's syndrome, and 1 with Simmonds' disease. The effects on the absolute lymphocyte count were determined. The normal patients and the three with Addison's disease Cushing's syndrome and Simmonds' disease all reacted similarly with an 18.3 per cent drop in lymphocytes. The diabetic patients showed a 43.2 per cent drop in lymphocytes. The authors found no correlation with the sugar curves. The only exceptions to the above findings were two psychoneurotic cases.

R.C.C.

THE CORRELATION OF THE CIRCULATING POLYMORPHONUCLEAR LEUCOCYTES (NEUTROPHILS) WITH THE ADRENAL ASCORBIC ACID IN THE RAT. *A. Day*. From the Department of Physiology, The George Washington D. C. Endocrinology 43 336-348 1948.

The purpose of this work was to determine whether there was any correlation between the amount of ascorbic acid in the adrenals and the number of circulating neutrophils. Sprague Dawley rats were used. In the normal rats the number of neutrophils decreased as the amount of ascorbic acid increased, thus a negative correlation. The lymphocytes showed no such correlation. Injections of adrenalin decreased the ascorbic acid content of the adrenals but did not influence the neutrophils or the lymphocytes in a similar way. Twenty hours after the adrenalin injection the correlation already mentioned for the normal animal was re-established. Urethane induced a lymphopenia but did not alter the circulating neutrophils or the ascorbic acid content of the adrenals. The authors suggest that the adrenal cortex regulates the number of circulating neutrophils to some extent.

R.C.C.

THE ADMINISTRATION OF ADRENOCORTICOTROPIC HORMONE TO NORMAL HUMAN SUBJECTS. THE EFFECT ON THE LEUCOCYTES IN THE BLOOD AND ON CIRCULATING ANTIBODY LEVELS. *P. H. Herbert and J. A. de Vries*. From the McGill University Clinic, Royal Victoria Hospital and the Department of Bacteriology McGill University Montreal Canada. Endocrinology 44 259-273 1949.

Circulating antibody levels in normal human subjects were not increased following the administration of 40-400 mg. of adrenocorticotrophic hormone. The findings of other workers, that the lymphocyte and eosinophil counts would decrease under such stimulation, were confirmed.

R.C.C.

ON THE FUNCTION OF MONOCYTES IN INFLUENZA VIRUS PNEUMONIA. *Kurt Ballenweiz* (I. Med. Universitätsklinik Charité Berlin). Ztschr. ges. Inn. Med. 1948 437-444.

A cell system is described which develops from inactive prestages of adventitial histiocytes in the medium sized vessels of the lungs under the influence of the irritating action of virus pneumonia. The cells are histiocytic monocytes characterized by the capacity of storing trypan blue in the living state, and by a peculiar arrangement and form within the granulation tissue. Pathologic forms of monocytes and segmented leukocytes in the peripheral blood are described. The vital staining reaction of this cell system is differentiated from the known properties of the reticulo-endothelial system of the liver.

C.M.

## PHYSIOLOGY OF COAGULATION

THE STABILITY OF AC GLOBULIN AND OF PROTHROMBIN IN CITRATED HUMAN PLASMA. *J. L. Fabry, A. G. Ware and W. H. Seegers*. From the Department of Physiology Wayne University College of Medicine, Detroit Michigan. Surg. Gynec. & Obst. 88 370-372, 1949.

Daily determinations were made of the concentrations of prothrombin and Ac globulin in stored citrated plasma and stored citrated whole blood. Prothrombin analysis was carried out by both the two-stage method and a modified two-stage method in which an optimum amount of Ac globulin is provided in the first stage.

The prothrombin content of citrated plasma stored at 5°C. remained constant for at least three weeks as determined by the modified method, whereas plasma Ac globulin concentration remained constant for seven days and then gradually decreased to about a third of the initial level by the third week. This

decrease in plasma Ac globulin approximated the apparent decrease in prothrombin level as determined by the unmodified two-stage method. The stability of prothrombin was unaffected by the presence of cellular elements but Ac globulin was found to be somewhat less stable in whole blood than in centrifuged plasma.

It would appear therefore that blood obtained from hospital blood banks contains its original concentration of prothrombin and that for ordinary use the decrease in Ac globulin is not sufficiently great to be of clinical significance.

H.W.B.

A SIMPLIFIED TECHNIQUE FOR THE DETERMINATION OF PROTHROMBIN TIMES. P. G. Schwager and L. B. Jaques. From the Saskatoon City Hospital and the Department of Physiology University of Saskatchewan, Saskatoon, Saskatchewan. *Canad. M. A. J.* 60: 258-261, 1949.

A simple method for determination of prothrombin time, which has been found satisfactory in the regulation of patients on dicumarol therapy during a two year period is described. In this procedure, whole blood is added at the time it is drawn to thromboplastin. The method was standardized in terms of per cent of prothrombin by taking blood in silicone and preparing a series of red cell-plasma mixtures containing varying dilutions of plasma. (The plasma diluent is not stated.) Preparation of thromboplastin for the individual determinations is described.

This method is recommended for use in office practice and smaller hospitals. In view of the limitations of prothrombin determination as done by generally accepted methods, however, the advantages of simplicity, rapidity and elimination of the necessity for recalcification in this test would appear to warrant its further investigation in dicumarol treated patients.

H.W.B.

THE USE OF RUSSELL VIPER VENOM AND LECITHIN AS THROMBOPLASTIN IN THE ESTIMATION OF PROTHROMBIN. C. A. Mason. From the Pathological Laboratory, Royal Berkshire Hospital, Reading, England. *J. Lab. & Clin. Med.* 34: 458-472, 1949.

Estimations of prothrombin in dicumarin plasma have been compared using the two-stage procedure of Warner, Brinkhous and Smith (modification of Herbert), the one-stage method of Quick, and a one-stage method in which Russell viper venom and lecithin were used as the thromboplastin. The two-stage method gave results in fair agreement with those obtained with the one-stage viper venom method. When rabbit brain or ox lung was used the prothrombin concentration was found to be lower than that given by the other two methods. Using the venom-lecithin method the authors found that hemorrhage was unlikely if the plasma prothrombin was kept above 30 per cent of the normal value.

ENZYME STUDIES ON HUMAN BLOOD. III. EFFECT OF PLASMA PROTEINS ON COAGULATION. G. Y. Shimamura. From the Department of Pathology, College of Medicine, The Ohio State University, Columbus, Ohio. *J. Lab. & Clin. Med.* 34: 477-481, 1949.

In a previous publication the author demonstrated that the clotting time of a thrombin-fibrinogen system became elevated as the purity of the fibrinogen preparation increased. This observation prompted the author to study the effect of albumin fraction II, III, fraction IV, and hemoglobin on the thrombin-fibrinogen reaction time. It was found that albumin definitely lowers fractions II, III and IV, and fraction IV-4 and hemoglobin slightly depress the clotting time in a system of fibrinogen fractions in citrate-phosphate buffer.

ENZYME STUDIES ON HUMAN BLOOD. IV. INTERRELATION OF HEPARIN AND FIBROGEN FRACTIONS. G. Y. Shimamura. From the Department of Pathology, Ohio State University College of Medicine, Columbus, Ohio. *Am. J. Physiol.* 154: 458-464, 1949.

The effect of heparin on fibrinogen fractions prepared by low salt low temperature-ethanol procedure was studied. As small an amount of heparin as 0.01 mg. without added cofactor had a measurable coagulant effect on 100 cc. of Seitz filtered fibrinogen fraction. On fibrinogen fraction solutions which were not filtered, variable but reproducible effects were obtained. These varied with the concentration of

of added heparin. The author concludes that this phenomenon suggests the presence of another factor (P) which is necessary for the production of coagulant effects of heparin in fibrinogen fractions.

**A PROTAMINE TITRATION AS AN INDICATION OF A CLOTTING DEFECT IN CERTAIN HEMORRHAGIC STATES**  
J G Allen P V Moulder R M Elghammer B J Grossman C L McKen M Sanderson W Eger and J M Crosby From the Department of Surgery and the Argonne National Laboratory of the University of Chicago Chicago Illinois J Lab & Clin Med 34 473-476 1949

A method for the determination of heparin like substances in blood is described in detail. This method is based on the fact that when heparin is added to blood and the clotting time begins to increase very small increments of heparin then markedly prolong the clotting time and when these increments are plotted against the clotting times the curve obtained for normal blood is a typical first order curve. Thus in order to make use of the more sensitive portion of the curve blood specimens were made incoagulable by the addition of a standard amount of heparin and then back titrated with a standard solution of protamine sulfate to a clotting end point. Theoretically the amount of protamine sulfate required in such a system to re-establish coagulation would vary in accordance with the concentration of the native heparins and antiheparins of the sample other factors being normal. The protamine requirement under standard conditions was found remarkably constant in both man and dog. Sources of error and the limitations of the method are discussed. In a future publication the authors plan to present their results in certain hemorrhagic states using this method.

## LEUKEMIA

**CHRONIC LYMPHATIC LEUKEMIA. A STUDY OF 100 PATIENTS TREATED WITH RADIOACTIVE PHOSPHORUS**  
J H Laurence B V A Law-Ber and J W J Carpenter From the Radiation Laboratory and Divisions of Medical Physics (Donner Laboratory and the Department of Physics) and Radiology University of California Berkeley Calif J A M A 140 585-588 1949

The authors are impressed with the ease and satisfactory perhaps encouraging results of the treatment of patients with chronic lymphatic leukemia by means of internal irradiation with  $P^{32}$ . The dosage used was 1 to 2 millicuries per week for from four to eight weeks repeated subsequently whenever the disease relapsed. There was a small increase in the average duration of life under this treatment as compared with the use of x ray alone.

S.E.

**SPONTANEOUS REMISSION IN ACUTE LEUKEMIA. REPORT OF A CASE COMPLICATED BY ECLAMPSIA**  
R F Borg A L Jenks Jr and S K Davis From the Departments of Pathology and Internal Medicine Iowa Methodist Hospital Des Moines Iowa J A M A 140 589-592 1949

The authors collect 11 cases of spontaneous remission of acute leukemia in the literature of which 4 were in children (all females) 3 in adult males and 4 in adult females. The duration of remission ranged from 2 to 24 months (authors' patient). One case showed two separate remissions. In all cases as well as the authors' the eventual outcome was death.

The authors detail the story of the eleventh case a woman of 33 who developed acute leukemia in the seventh month of pregnancy and who at the same time developed eclampsia. One month after the delivery of a stillborn baby the patient had spontaneously improved to a point at which there was complete normality of physical examination blood count and bone marrow smears. She was well for the following twenty-one months when she rather suddenly relapsed and within three weeks died despite treatment. Autopsy showed leukemic involvement of bone marrow and spleen.

**FORMATION OF CRYSTALS IN THE CORNEA DURING URETHANE MEDICATION OF MYELOMA**  
N Markoff (Medical Department Hospital of Chur Switzerland) Schweiz. med. Wchnschr. 73 987-988 1948

Deposition of crystals in the cornea occurred during urethane medication of myeloma. As formation of crystals may be found in different organs in myeloma the author asks whether these crystals are so called myeloma crystals or urethane crystals. The fact that they disappeared when the urethane medication ceased seems to speak in favor of the latter.

## SPLEEN

A CONSIDERATION OF THE BANTI SYNDROME *P F Wagley* From the Department of Medicine The Johns Hopkins University and Hospital Baltimore Md Bull Johns Hopkins Hosp 83 87-114 1949

Banti's syndrome is reviewed in terms of history laboratory data pathogenesis splenic pathology clinical course and therapy One hundred and thirty three references to the literature are included The author concludes that although splenic vein hypertension has been frequently seen in this condition and may be associated with a variety of abnormalities in the splenic and portal vasculature, the role such hypertension plays other than leading to the formation of gastrointestinal varices and subsequent blood loss is unexplained The evidence for the two most commonly suggested roles of the spleen—namely (1) indiscriminate phagocytosis and (2) humoral inhibition of marrow hemopoiesis is reviewed Therapy is discussed from both the medical and surgical aspects No detailed comparison of results of portal shunt procedure with the procedure of simple splenectomy is made

W N V

PRIMARY SPLENIC PANNHEMATOPENIA *R W Heinle and W D Helden* From the Departments of Medicine and Surgery, University Hospitals of Cleveland and Western Reserve University Cleveland Ohio Surg Gynec & Obst 89 79-91 1949

Seven patients with splenomegaly hyperplastic bone marrow neutropenia anemia and thrombocytopenia were studied before and after splenectomy Evidence that the anemia was clearly hemolytic in nature was lacking With the exception of one patient who died soon after splenectomy from other causes all showed marked although in most instances gradual improvement following splenectomy Examination of the spleens revealed varying degrees of follicular hyperplasia Splenic phagocytic activity of any significance could not be demonstrated in supravital Wright stained or fixed tissue preparations

The authors believe that the findings in primary splenic pannerhematopenia are best explained by the theory that the spleen has some regulatory action on the bone marrow Doubt is cast on the concept that congenital hemolytic anemia and idiopathic thrombocytopenic purpura are members of this syndrome

*Symposium de Hematologica y Hemoterapia 1948* By J GUASCH A RAICHS C TRINCAO AND R SURINTACH.  
Barcelona Editorial Minguel Servet 1949 522 pages

This book contains seven sections some of them developed at considerably greater length than is customary in this country on the following subjects penicillin in the treatment of neutropenias (recommended) the treatment of kala azar by splenectomy (recommended in certain cases because the spleen acts by depressing marrow activity) elliptocytosis in man (discussed in great detail classified on none too secure grounds into constitutional elliptocytosis and no less than eleven atypical forms and compared with the occurrence of elliptical cells in the camels, the conclusion is that oval red cells in man and in the camels are similar in a superficial way only) leukemia in pregnancy (2 cases with a précis of cases already described) the blood picture in allergy (eosinophilia the most constant feature) the distribution of the Rh factor in Spain (high percentage of Rh negatives in Belgium and in the north of Spain local variations in Spain not statistically impressive) and the administration of drugs etc., via the bone marrow (recommended with many contraindications most of which are already recognized)

Each section has an English summary All the sections are written from an essentially clinical and morphologic point of view and the extensive bibliographies will appeal to those who like discussions to be thoroughly documented

### THE PROTHROMBIN CONSUMPTION TEST ITS CLINICAL AND THEORETIC IMPLICATIONS

By ARMAND J. QUICK, M D , AND JEAN E. FAVRE-GILLY, M D

IN 1947, a simple procedure was described for estimating the available thromboplastin of the blood, which was named the prothrombin consumption test<sup>1</sup>. It is based on the principle that by determining the prothrombin before and after coagulation is complete, a measure of the plasma thromboplastin that reacts with prothrombin is obtained. By means of this test it was established that little prothrombin is consumed in the clotting of either hemophilic blood or platelet-depleted plasma.

In the original test, blood was allowed to remain one hour at 37 C. after coagulation before the prothrombin of the serum was determined. While satisfactory results were obtained with hemophilic and thrombocytopenic bloods, occasional inconsistencies were encountered that could not be explained. In searching for the cause of these aberrant results, the important finding was made that when normal blood clots in a test tube, all of the fibrinogen is converted to fibrin before a detectable diminution of prothrombin occurs.<sup>2</sup> This leads to the logical conclusion that the fibrin clot, being uniformly dispersed through the mass of blood, presents an enormous adsorbing surface which quickly and effectively removes the nascent thrombin, thereby preventing sufficient accumulation to initiate the chain reaction that is mediated through the labilizing action of thrombin on the platelets. Almost all of the consumption of prothrombin therefore occurs only after the serum has been separated from the clot either mechanically by centrifugation, or spontaneously through clot retraction.

As a result of the observation that prothrombin consumption is markedly influenced by the separation of serum from the clot, the original test was modified in order to control the adsorption factor of fibrin. Instead of waiting one hour after coagulation before determining the prothrombin of the serum, several test tubes, each containing the same volume of blood, were allowed to coagulate. Every fifteen minutes a tube was centrifuged and the prothrombin of the serum determined at once and after fifteen minute intervals. Since the conversion of prothrom-

From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wis.

This work was supported by a grant from the Division of Research Grants and Fellowships of the National Institute of Health, United States Public Health Service.

bin is very rapid immediately following the break in the intimate contact of the serum with the fibrin reticulum, thrombin will form and accumulate during centrifugation, therefore the prothrombin time done directly will be abnormally short, since it measures thrombin already present plus the amount formed during the test. By adding sodium citrate to the clotted blood just prior to centrifugation, thrombin formation is stopped, and a true prothrombin value in serum is obtained.

### METHODS

The prothrombin consumption test requires the same reagents as the original one-stage method for determining prothrombin.<sup>2</sup> The thromboplastin is prepared from acetone-dehydrated rabbit brain which consistently yields a prothrombin time of 11 to 12½ seconds for normal human plasma.

*Tricalcium phosphate treated plasma (calcium phosphate plasma)* Tricalcium phosphate quantitatively removes component A from oxalated plasma. It does not remove the labile factor nor fibrinogen; therefore calcium phosphate plasma serves as a ready and convenient source of fibrinogen when determining the prothrombin of serum.

Calcium phosphate plasma is prepared as follows. A measured volume of a 0.005 M suspension of tricalcium phosphate (1 cc. for every cc. of oxalated plasma to be treated) is transferred to a test tube. By centrifuging the gelatinous calcium phosphate is packed and the surplus water poured off. The required volume of fresh oxalated human plasma is added, mixed with the adsorbant and repeatedly stirred with a small glass rod for five minutes at room temperature. The calcium phosphate is removed by centrifugation and the clear adsorbed plasma poured into a clean test tube.

*Prothrombin time of serum* The calcium phosphate plasma (0.1 cc.) is mixed with 0.1 cc. thromboplastin and 0.1 cc. of 0.02 M calcium chloride. Into this mixture 0.1 cc. of the serum is blown by means of a serologic pipet and the time required for a clot to form accurately determined.

*The prothrombin consumption test* Blood obtained by venipuncture is distributed in 2 cc. portions to 8 test tubes (100 x 13 mm.). These are placed in a water bath at 37 C. The time required to form a solid clot is noted and fifteen minutes later 0.1 cc. of 0.4 M sodium citrate is added to one tube. This and a second tube are put in an International Clinical centrifuge and spun at full speed for one minute. After an additional half minute required to stop the centrifuge the prothrombin time is immediately determined in the noncitratd serum and then in the citrated serum. For the latter 0.04 M calcium chloride is used. The prothrombin time of the two sera is determined for three consecutive fifteen minute periods. Thirty minutes after coagulation 0.1 cc. of 0.04 M sodium citrate is added to tube 3, which with tube 4 is centrifuged and the prothrombin time of the serum determined immediately and for two additional fifteen minute periods. At the end of forty five minutes following coagulation tubes 5 and 6 are taken out of the water bath; to one sodium citrate is added and both centrifuged and the prothrombin determined. At sixty minutes tubes 7 and 8 are similarly treated.

For ordinary clinical studies it may not be necessary to follow the prothrombin consumption test in 8 test tubes. Three tubes will suffice. The first is centrifuged fifteen minutes after coagulation, the second after thirty and the third after sixty minutes. The prothrombin time is determined in each tube immediately after centrifugation and every fifteen minutes within the first hour after coagulation.

### RESULTS AND DISCUSSION

*Prothrombin consumption in the clotting of normal blood* In table 1 the prothrombin consumption observed in two typically normal healthy subjects is presented. It will be observed that in subject 1, the consumption of prothrombin is considerably slower and less complete than in subject 2. Thus, in the first individual only 50 per cent of the prothrombin was consumed in thirty minutes, whereas 70 was converted in the second during that period. At the end of one hour, the maximum quantity of prothrombin converted in the serum of subject 1 was approximately 85 per cent, whereas 95 per cent was consumed in the serum of subject 2.

Such marked variations in the activation are interesting, because the concentrations of the factors that constitute the prothrombin complex are remarkably constant in normal healthy individuals. It will be important to study these differences in the availability of thromboplastin as determined by the prothrombin consumption in relation to thrombotic tendencies. While it has been postulated since the time of Virchow that hypercoagulability of the blood is one of the triads that causes thrombosis, no reliable evidence can be found for its support. Hypercoagulability as determined by the coagulation time is not only meaningless, but occasionally definitely erroneous, as will be brought out in the discussion of thrombocytopenia. Since the prothrombin consumption test offers a new and

promising means to determine the thromboplastin factors quantitatively, its value in postoperative or other conditions in which intravascular clotting commonly occurs will be investigated.

*The prothrombin consumption in hemophilic blood.* Evidence has accumulated since the time of Alexander Schmidt that the defect in hemophilia is a lack of thromboplastin. But Addis<sup>4</sup> believed that the coagulation defect in hemophilia was due to a qualitative change in prothrombin which was responsible for its slow conversion to thrombin. Eagle<sup>14</sup> presented evidence showing that the platelets were functionally normal as well as the prothrombin, but that its activation was delayed for which he could offer no adequate explanation. Brinkhous<sup>15</sup> was the first to study quantitatively the rate of prothrombin conversion in hemophilia and to

concluded that reaction was very slow. This he attributed to the sluggishness with which the formed elements of the blood liberate thromboplastin. More recently, he<sup>6</sup> has postulated that hemophilic blood lacks a factor which is required for the lysis of platelets. In contrast to this explanation, Quick has postulated that the agent responsible for platelet lysis is thrombin itself and that the basic defect in hemophilia is the lack of thromboplastinogen. The platelets have been found entirely normal. Their seeming stability is due to the lack of thrombin formation caused by the deficiency of thromboplastinogen. The new concept introduced by Quick is that platelets do not furnish thromboplastin, but the enzyme which activates plasma thromboplastinogen.

\* Prothrombin determined immediately after centrifugation.

† Sodium citrate added to coagulated blood immediately before centrifugation.

A study of the prothrombin consumption of two hemophiliacs is given in table 2. The data are typical. Similar results have been obtained on 20 other hemophilic patients.<sup>6</sup> Oddly, the prothrombin consumption time immediately after the clotted blood is centrifuged becomes fixed and often does not change in twenty-four hours or longer. Frequently the serum prothrombin time is shorter than that of the oxalated plasma and the usual range is nine to twelve seconds. This shortening of the prothrombin time does not occur until thrombin has accumulated, for on adding sodium citrate prior to centrifuging, to the clotted blood, a normal prothrombin of eleven to twelve seconds is obtained.

The diagnostic value of the prothrombin consumption test in hemophilia is obvious. It is particularly helpful in the diagnosis of the disease in very young children who present difficulties in the collection of blood completely free of tissue juice contamination. Often the diagnosis is delayed for months and even years because of failure to obtain a prolonged coagulation. This actually happened in the case of the second patient. The correct diagnosis was not made until he was

nearly seven years old. In one hospital his condition had been diagnosed as purpura and a splenectomy advised.

*The prothrombin consumption in thrombocytopenic purpura.* Since it was found that the removal of platelets from plasma markedly inhibited the conversion of prothrombin, it could be anticipated that a faulty or delayed prothrombin consumption occurs in thrombocytopenic purpura. This was verified with clinical cases by Soulier<sup>7</sup> and by Quick, Shanberge and Stefanini.<sup>8,9</sup> The latter studied one case in which the prothrombin consumption time improved as the platelets increased and clinical recovery occurred and another case in which splenectomy caused a rapid recovery as indicated by the platelet count and the prothrombin consumption test. In those studies the one hour old serum was employed.

\* Prothrombin determined immediately after centrifugation

† Sodium citrate added to unretracted clot immediately before centrifugation

In the present investigation several cases were studied by the new technic. The results obtained on 2 of these cases are presented in table 3. It is clear that when the platelet count is low, little prothrombin is converted, but the prothrombin consumption time is not as fixed and constant as in hemophilia. It tends to increase as the serum stands. There is apparently a slow conversion of prothrombin which is to be expected if the hypothesis is correct that the platelets liberate the activating enzyme of thromboplastinogen.

Since a close relationship exists between the platelet count and the prothrombin consumption, the latter test complements the platelet count and can probably be substituted for it when the latter is not available. Since the recognition of thrombocytopenic purpura is relatively simple, the test very likely will contribute little diagnostically. It may, however, become helpful in the condition in which a qualitative change in the platelets exist. Such a condition has been postulated but never satisfactorily demonstrated by concrete tests and experiments.

The most important contribution that the prothrombin consumption test has made to the problem of thrombocytopenic purpura is the establishment that a

demonstrable defect in coagulation occurs despite the normal coagulation time. There is good evidence clinically that neither the low platelet count nor the defective prothrombin consumption is responsible for the petechiae, the ecchymosis or the mucous membrane oozing. These are due to damage or dysfunction of the capillaries caused perhaps by a specific agent. It is logical to suppose, however, that the coagulation defect arising from the thrombocytopenia superimposed on the capillary hyperpermeability accentuates the hemorrhagic state.

*The prothrombin consumption in hypoprothrombinemia.* Since the discovery in 1943<sup>10</sup> that prothrombin activity is not confined to one discrete compound, but to several factors which have been designated as components of the prothrombin complex, the problem has become rather complicated. There is a growing agreement that one of these factors diminishes fairly readily on storage, and is not adsorbed by tricalcium phosphate. This agent has been named the labile factor by Quick. The second factor, component A, is adsorbed by tricalcium phosphate, disappears from the blood in vitamin K deficiency, is probably inactivated by sodium citrate, and is diminished in one type of congenital hypoprothrombinemia.<sup>11, 1</sup> The third factor, component B, is least clearly defined.\* Its existence is postulated to explain the type of hypoprothrombinemia that is both congenital and hereditary and in which no deficiency in the labile factor nor component A occurs.<sup>11, 12</sup> Most characteristic in this type of hypoprothrombinemia is the fixed prothrombin level. In one family the prothrombin time is consistently sixteen seconds in the mother and in a daughter and in one son. Recently a second family has been studied in which the prothrombin time is fixed at fourteen seconds and has appeared in three generations.

In table 4 are recorded the prothrombin consumption tests observed in the blood of a patient treated with dicumarol and in a boy suffering from a congenital deficiency of component A. The prothrombin consumption in the latter is strikingly complete. Fifteen minutes after the clotted blood was centrifuged the prothrombin time of the serum increased to 155 seconds which represents 2 per cent of prothrombin activity. In marked contrast, the blood from the patient on dicumarol therapy which had a prothrombin time of twenty five seconds showed a relatively poor conversion of prothrombin during coagulation. These results cannot be satisfactorily explained until more is known concerning the interaction of the various components of the prothrombin complex. Until such information becomes available the results of a prothrombin consumption test in hypoprothrombinemia will be difficult to interpret and the test will be of limited value clinically.

*The relation of prothrombin consumption to hemostasis.* The most remarkable finding that has accrued from this investigation is that in the test tube only a minute amount of prothrombin is converted to thrombin in the coagulation of all the

\* Since the manuscript was submitted it has been shown (Quick, A. J. and Stefani, M. The state of component A [prothrombin] in human blood. Evidence that it is partly free and partly in an inactive or precursor form. *J. Lab. & Clin. Med.* 34: 1203, 1949) that human plasma contains free and an inactive prothrombin. It is probable that component B is concerned with the conversion of the prothrombin precursor to the active state.

fibrinogen of the blood. Even after the clotted blood has remained in the water bath for fifteen minutes or longer, so little prothrombin is utilized that the amount cannot be estimated. It is only after separation of the serum from the clot takes place that prothrombin begins to decrease rapidly. Obviously fibrin, itself, is the most important physiological anti-thrombin. Potentially, 1 cc. of blood can yield enough thrombin to coagulate all the blood of the body. Heretofore, it was difficult to explain how this powerful latent clotting capacity of the blood was held in check. It is now clear that the strong adsorptive property of fibrin not only guards against the accumulation of thrombin, but also prevents the autocatalytic reaction involving the lability of platelets by thrombin from being set in motion.

\* Prothrombin determined immediately after centrifugation

† Sodium citrate added to unretracted clot immediately before centrifugation

In the test tube left undisturbed no significant change in the prothrombin concentration occurs until clot retraction takes place. But this phenomenon as observed in a test tube is purely artificial since the walls are rigid and unlike the more elastic walls of a vein. Clot retraction as seen in a test tube has not been demonstrated *in vivo* and, furthermore, its physiological significance is not known. To be sure, Quick in his monograph<sup>12</sup> presented a pen drawing to show how clot retraction might draw in the torn edges of an injured vessel and thus anchor the fibrin clot. Seegers and Sharp<sup>14</sup> apparently were sufficiently impressed with this concept to reproduce it as a color plate. Unfortunately the interval for which the contracts the clot is weak, and it is difficult to see how this mechanism could function in arteriolar bleeding since such a vessel has not enough fluid to permit a weak force to narrow the lumen. It seems fairly certain that no retraction of separation of serum occurs in intravascular clotting and that the conversion of prothrombin to thrombin takes place *in vivo*.

It would be idle even in the light of these new observations to speculate how hemostasis is achieved, but a few possible suggestions can be offered. Platelet accumulation and agglutination at the site of injury is undoubtedly the early response as Zucker<sup>15</sup> convincingly has shown. As soon as platelets disintegrate thrombin is produced and some fibrin must form. As platelets are lysed, a vasoconstrictor is liberated which contracts all the vessels in the affected area, thus sharply localizing the process. A clot enmeshing the formed elements of the blood, including platelets, will form in the traumatized area. Due to the antithrombic action of fibrin, little thrombin becomes available to labilize platelets, therefore the disintegration of these cells is slow, and the liberation of the vasoconstrictor principle minimal but sustained. The possibility that the fibrin clot is more than a mechanical plug cannot be ignored. It is likely that the fibrin reticulum is the means whereby the coagulation reaction is held in check and that by this means the conditions for sustained hemostasis are maintained.

### SUMMARY

The prothrombin consumption test, which originally was carried out on serum one hour after coagulation, is modified. Blood is distributed to several test tubes, and after fixed time intervals, the tubes are centrifuged. The prothrombin of the serum of each tube is determined immediately, and every fifteen minutes within the limits of one hour from the time the blood is taken.

The prothrombin consumption shows considerable variations in normal individuals. In hemophilia and in thrombocytopenia it is very incomplete. In hypoprothrombinemia the prothrombin may be very complete as in congenital hypoprothrombinemia of the Component A deficiency type, or surprisingly incomplete as in dicumarol hypoprothrombinemia. The possible significance of prothrombin consumption in relation to hemostasis is discussed.

# THE CHAIN REACTION OF THE BLOOD CLOTTING MECHANISM IN RELATION TO THE THEORY OF HEMOSTASIS AND THROMBOSIS

By J H MILSTONE, M D

## THE PHYSIOLOGIC REQUIREMENT

IF OCCASION arose to invent a blood clotting mechanism, it might be arranged for the blood to remain fluid in the vessels, yet promptly congeal when mixed with the juice of freshly cut tissue. This would probably work well for small punctures. However, as this mechanism was tested with larger cuts, an unexpected difficulty might appear. As the blood flowed through the break, a coagulated film would be deposited on the cut surface. This layer would seal over the wounded tissue and hinder the admixture of tissue juice with that portion of blood not yet clotted. Therefore, hemorrhage would continue through a passageway lined by freshly clotted blood.

To overcome this difficulty a chain reaction might be introduced. Then, as one layer of blood was clotting, it would incite the neighboring layer to clot. Thereby the coagulation process could be propagated from one layer to the next, and tissue juice would be needed only to exert its effect on the initial layer. The mechanism could then achieve a hemostatic plug which would grow by accretion, and which, in this respect, would resemble the natural plug depicted by Tocantins.<sup>1</sup>

Thus, by teleologic conjecture, we have arrived at some function a chain reaction might serve. Other functions can be imagined. Ordinary chemical reactions, be they stoichiometric combinations or enzymatic, begin rapidly and thereafter slow down. But, when a chain reaction is involved, one of the products accelerates the reaction, with the result that as more product is formed the reaction goes increasingly faster.\* Hence, chain reactions may start with a lag period, but later are apt to proceed explosively. This offers opportunity for control during the lag period, but ensures rapid action when the lag has been passed or overcome.

## THE BIOCHEMICAL MECHANISM

Whatever its prime function, a chain reaction does occur during the coagulation of blood. An experiment in which the clotting process was transmitted through a series of plasma samples was described by Gratia in 1922.\* Once the process had

From the Laboratory of Pathology, Yale University School of Medicine, New Haven, Conn.

This work was aided by a grant from the James Hudson Brown Memorial Fund of the Yale University School of Medicine.

\*The concept of chain reaction was originally introduced in connection with the photochemical combination of hydrogen and chlorine. It has been broadly applied to various series of consecutive reactions which repeat themselves over and over again. When, in addition, the reaction velocity increases as described by Glasstone (Glasstone, S. Textbook of Physical Chemistry, ed. 2, New York: D. Van Nostrand Co., Inc., 1946, p. 1083), then the chain is said to be nonstationary. It is this type which is implied throughout the present discussion. Here the terms chain reaction and autocatalytic effect are used in order to include other possible mechanisms besides a simple autocatalytic reaction, and autocatalytic reactions are regarded as a special group of nonstationary chain reactions.

been initiated in the first tube, each tube of fluid plasma was caused to clot by seeding it with a few drops of serum from the preceding tube. In 1935, Fischer,<sup>2</sup> apparently unaware of Gratia's previous discussion, reported similar serial passage experiments with minor differences in technic and results. Gratia was impressed by the formal resemblance between the propagation of bacteriophage and the propagation of the clotting process with repeated new formation of thrombin. Fischer wrote of blood coagulation as an endlessly transmissible chain reaction.

Although these demonstrations were spectacular, they were not the first indications of the autocatalytic effect. Beginning in the nineteenth century, two complementary approaches have been made to the analysis of coagulation mechanism: (a) Separation of coagulation factors; (b) separation of individual reactions.

FIG. 1.—SOME EVENTS OCCURRING WHEN BLOOD CLOTS IN A GLASS TUBE. The chain reaction is the kind of process which could cause the growth of a hemostatic plug and the propagation of a thrombus.

The decreases in thrombokinas activity, thrombin and fibrin illustrate the antithrombotic antithrombin and fibrinolytic effects respectively. Such reactions may help to limit the growth of a hemostatic plug or of a thrombus.

This type of synoptic diagram does not appear to have been attempted before and modifications will probably become necessary as more data are obtained. The broken line representing platelet changes is based on observations less pertinent than is the case for the three continuous curves. The historical and experimental background is outlined in the text. (Figure prepared by Mr. Armin H. Rieberger)

By 1904, this twin approach had developed far enough to engender the classic two stage theory

1. Prothrombin  $\rightarrow$  Thrombin In the presence of thrombokinase and calcium
2. Fibrinogen  $\rightarrow$  Fibrin In the presence of thrombin

2. Fibrinogen  $\rightarrow$  Fibrin In the presence of thrombin. But, beginning before 1904, and continuing into the present results have been obtained with separated factors and separated reactions which show that the simple two-stage concept must be modified. And all along the line there have been repeated intimations of autocatalysis. Many studies have been made of the rate at which the coagulation products appear. A frequent finding has been a lag period followed by a period of accelerated production—characteristics of a chain reaction. This is illustrated in figure 1, which outlines the events that occur when blood clots in a glass tube. Actually such a complete experiment has never been

done, and the diagram is a tentative, rough summary of data obtained in various ways

During the performance of the routine test for clotting time, and when the blood is normal, the impression is gained that very little physical change takes place until the end point is imminent. Then, in a comparatively brief interval, the viscosity rapidly increases and a solid clot forms. This gross impression has been confirmed by finer methods, and the production of fibrin is accordingly represented in the diagram. At the time the solid clot appears, less than half the fibrinogen has been converted to polymerized fibrin. As this production of fibrin continues, the clot becomes firmer. After a half-hour or more, the clot retracts. Then, on standing many hours, the amount of the fibrin diminishes somewhat, as can be determined by weighing. This last effect is due to the action of one or more fibrinolytic enzymes, and represents only a partial development of the fibrinolytic potential of the blood. Normally, the enzyme is kept for the most part in an inactive state. As a result of disease or artificial manipulation, fibrinolytic activity can be developed to a surprising degree.<sup>4, 5</sup> It is a remarkable fact that blood normally contains enough potential fibrinolytic activity to liquefy its own clot. For reasons only partially understood, the fibrinolytic potential is rarely, if ever, developed to the full.

The explanation for the shape of the fibrin curve may be complex in detail, but the main reason for its late start is that, up until that time, there is not enough thrombin to clot the fibrinogen. This delay was reported in 1901 by Arthus,<sup>6</sup> who further noted the accelerated production of thrombin just before the clot appeared. Soon the amount of thrombin dwindles—the antithrombin effect.

Carrying the discussion one step further, the delay in thrombin formation is due to the fact that sufficient thrombokinase activity must first be developed. Reasoning from simple experiments on whole blood, Collingwood and MacMahon concluded in 1912<sup>7</sup> that a large part of the clotting time was spent in developing thrombokinase from an inactive precursor which they called prothrombokinase. Recently, by separating the coagulation process into three stages, carried out in three successive sets of test tubes, it has been possible to show that thrombokinase activity develops as shown in figure 1.<sup>8</sup> The latent period and the period of acceleration still suggested a chain reaction, an interpretation corroborated by seeding experiments. There was further noted a prompt and rapid loss of thrombokinase activity, another result foreshadowed by the work of Collingwood and MacMahon.

These are not isolated findings. Using different technical approaches, the interpretations of several recent investigators<sup>9-12</sup> are virtually unanimous on the following broad conclusions: (a) The coagulation mechanism comprises at least three distinct reactions. (b) A chain reaction is involved in the production of a factor that can accelerate the activation of prothrombin.

Contemporary literature, however, shows that these basic findings can be elaborated with greater diversity than might be supposed. The diversity stems partly from the fact that terms like thrombokinase and thromboplastin are used in different ways and that several new terms have been introduced. More

important is the uncertainty concerning which and how many factors participate in the direct activation of prothrombin. Beyond this is the question of which factors, now thought to activate prothrombin, really do something else, such as accelerate the development of thrombokinase. How many different chain reactions occur? To date no convincing evidence has been presented either for or against the occurrence of a simple autocatalytic reaction (e.g.,  $x$  accelerates the production of  $x$ ). Seegers and his associates<sup>15</sup> have brought forth impressive, although not quite conclusive, evidence in favor of a more complicated chain (e.g.,  $x$  accelerates the production of  $y$ , which in turn accelerates the production of  $x$ ).

It is possible to summarize the present situation so as to emphasize the similarities of individual viewpoints rather than their differences.

- 1 Prothrombokinase Complex  $\rightarrow$  Thrombokinase Complex. An autocatalytic or chain reaction results in the acceleration of this conversion.
- 2 Prothrombin  $\rightarrow$  Thrombin. In the presence of the active thrombokinase complex.
- 3 Fibrinogen  $\rightarrow$  Fibrin. In the presence of thrombin.

This is an oversimplification, attained by neglecting details, and by grouping in the thrombokinase complex all factors, including calcium, which may be found to participate directly in the activation of prothrombin.

For the present discussion there are important differences between this formulation and the old two-stage theory. It may be emphasized that the necessary substances for these three stages of blood coagulation are present in, and obtainable from, the blood. The prothrombokinase complex is demonstrably different from the thrombokinase complex, and the conversion from the inactive form to the active form has been followed experimentally.\* This conversion is of further significance in that it consumes a large part of the time required for blood to clot in a glass tube. Moreover, the autocatalytic effect is concerned with the development of thrombokinase activity.\* As a consequence, a small amount of coagulating blood can, when mixed with unclotted blood, accelerate the first of the three reactions, and get the clotting process off to a good start in the fresh portion of blood.

Thus we have rather detailed biochemical evidence of a chain reaction which can take place entirely within the blood, and which can propagate the clotting process.

## THE ROLE OF THE THROMBOCYTES

This advance, although not yet consolidated, is already reaching out to include the thrombocytes. On the experimental side it appears that the chain reaction will proceed in the absence of whole platelets. This does not prove that material derived from platelets is not involved, or that whole platelets are not concerned when they are present. In his review on platelets, Tocantins<sup>16</sup> states the general impression that they will cause changes in the plasma which in turn will lead neighboring platelets to alter, and so on.

The platelet lysis and fusion observed in coagulating blood are brought about not simply by contact with glass in the presence of calcium, but require particularly the presence of a heat-labile factor found in the serum globulins. The serum factor was demonstrated by Wright and Minot in 1917.<sup>17</sup> Brinkhous,<sup>18</sup> on the basis of different considerations, has recognized what may be the same factor, and has suggested the name thrombocytolysin. How this is related to the other factors is not known, but it gives the means whereby the serum can change the platelets. In turn, the platelet material directly or indirectly exerts a pronounced acceleration on the production of thrombin.<sup>19</sup>

A reaction series, shuttling between platelets and plasma, could result in continuously renewed metamorphosis of platelets. Thus a white thrombus might be formed in flowing and eddying blood where fresh plasma and platelets would be supplied continuously to a stationary nidus of metamorphosed platelets. Conceivably this might be independent of the chain concerned in the development of thrombokinase, but there is much to suggest that the two chain effects are intimately related. Exactly how they are related and whether the platelets help or hinder the chain reaction is not known.

A further complexity cannot be ignored. The hemostatic plug, as well as the white thrombus formed in flowing blood, differ appreciably from the test tube clot or the red thrombus formed in stagnant blood. The former have a disproportionately high content of platelets, along with some fibrin (sometimes, apparently very little). Although the fibrin is probably a useful constituent, it is not certain that it is absolutely necessary. Various suggestions that transformed platelets may be sticky even in the absence of fibrin need to be corroborated. In this connection, it is curious that patients with congenital absence of fibrinogen are less incapacitated by their abnormality than is usually the case with haemophilia.<sup>20</sup> Phylogenetic comparisons have suggested that alterations of the thrombocytes represent a primitive component of the hemostatic mechanism, upon which fibrin formation has been superimposed. Be that as it may, even if two adhesive materials are used, it does not necessitate two entirely different mechanisms to apply them. And as yet, the facts do not compel us to postulate a separate chain reaction for platelet metamorphosis.

## THE PROBLEM OF REGULATION

How the chain reaction starts or whether it is always in progress and needs only to be brought to an effective intensity or critical concentration, is still a mystery. We are likewise ignorant of the precise mode of control. It is likely that the control

mechanism exerts not merely a static inhibition, but can also dampen the process when it is already under way. Otherwise, why would not a hemostatic plug or a fresh thrombus continue to grow until it incorporated all the blood in the cardiovascular system?

Several phenomena are known which result in the retardation of the clotting reactions or disposal of their products. Mere dispersion of coagulant products by an active circulation may be of great importance. In the test tube the rapid loss of thrombokinase activity is striking, and here the way is open for its further investigation.<sup>8</sup> If, as Quick<sup>12</sup> and Ware, Murphy and Seegers<sup>14</sup> believe, thrombin is an important link in the chain reaction, then both the antithrombokinase and antithrombin effects offer means for breaking the chain. The fibrinolytic enzyme(s) may accomplish more than is now appreciated. Heparin augments the antithrombin effect, and in some ways delays the activation of prothrombin. Although it is still uncertain whether heparin occurs in significant quantity in normal circulating blood, it appears to reach a highly anticoagulant level after anaphylactic shock and total body irradiation. There have been suggestions that other anticoagulant secretions are discharged steadily or in response to changes in the blood.

Suggestive data on the turnover of platelets, prothrombin and fibrinogen indicate that these factors are completely renewed every few days. It has been inferred that they are consumed in the usual blood clotting reactions, slowly proceeding in the circulation. This implies a degree of dynamic balance to maintain the fluidity of circulating blood, for the converted factors must be removed fast enough to prevent gross coagulation. As illustrated in figure 1 the antithrombokinase and antithrombin effects could take part in this balance. They inactivate coagulant products which have already been formed. Depending on quantitative relations, this kind of action could slow up the clotting process when it was already under way. Such action could help to limit the growth of a hemostatic plug to the requirements of physiologic necessity. The failure, or overpowering of such action might contribute to the excessive propagation of a thrombus.

It is quite possible that the critical juncture of the entire system is the development of thrombokinase activity. But detailed study of this has just begun.

reaction furnishes the biochemical basis for the propagation of a thrombus \* In biochemical experiments the chain reaction has long been in evidence In pathology the formation and propagation of a thrombus has been the subject of classic studies <sup>24</sup> One might speculate what the outcome will be as these data from different disciplines are brought together and extended The chain reaction is so intimately a part of the coagulation mechanism that it is likely to occur whenever a thrombus forms, unless the individual's blood is unusual Consequently, it would usually play some part in the extension of the thrombus The relative importance of its contribution in the genesis of various types of thrombi remains to be evaluated There may be some conditions where a thrombus would propagate even if there were no chain reaction, in some circumstances propagation might be impossible without one Of the latter case, the extension of a mural thrombus far into the chamber of the left ventricle might be an example

Here the growing surface is far from the injured myocardium, and the ventricular blood could hardly be called stagnant Is the continued deposition of platelets and fibrin sustained by diffusion of tissue factor through the thrombus? Or does it depend on repeated formation of fresh coagulant substances at the free surface, through operation of the chain reaction? Anticipation of this question is to be found in the statement of Solandt, Nassim and Best<sup>25</sup> It seems reasonable to suppose that, once agglutinating platelets have covered an injured region, the nature or degree of the underlying tissue damage will have little or nothing to do with subsequent growth of the thrombus The success of their pioneer experiments in suppressing cardiac mural thrombosis by heparinization emphasized anew that the state of the clotting system is very important This may include the chain reaction, but does not yet single it out as the *sine qua non* of cardiac mural thrombosis

#### SUMMARY A WORKING HYPOTHESIS

Detailed evidence has been accumulating that at least one chain reaction occurs during the coagulation of blood Both the metamorphosis of platelets and the development of thrombokinase appear to be involved The autocatalytic effect may serve a function in making possible the growth of a hemostatic plug It also offers advantages in the physiologic control of the clotting mechanism It is likely that the chain reaction occurs in most instances where a thrombus forms, and plays some part in its propagation

The chain reaction is a potentially explosive phenomenon which demands an adequate countermechanism With materials derived from blood, reactions have long since been demonstrated which can reduce thrombokinase activity, inactivate thrombin and liquefy fibrin These reactions may help to maintain the fluidity of the circulating blood by removing the products of smoldering clotting reactions

\* This question has been raised independently in two articles which appeared since the present paper was submitted for publication It was briefly mentioned by B Alexander A deVries and R Goldstein *Blood* 4: 739-746 1949 The idea and a discussion of its implications were presented by J H Mulstone *J Insur Med* 4: 5-7 July 1949 For a step toward the same idea see reference 15 page 74

Such effects could help to delimit the growth of a hemostatic plug, or to end the propagation of a thrombus.

While it is now possible to correlate in this way the data on blood coagulation with present knowledge of hemostasis and thrombosis, critical gaps in our understanding still remain.

# HYPOPROTHROMBINEMIA STUDIES OF A CASE OF THE IDIOPATHIC TYPE AND THE EFFECT OF SERUM ADMINISTRATION

By CHARLES L. CROCKETT, JR., M.D., DONALD SHOTTON, M.D., CHARLES G. CRADDOCK, JR., M.D., AND BYRD S. LEAVELL, M.D.

**H**EMORRHAGIC diathesis due to idiopathic hypoprothrombinemia was reported first in 1941 by Rhoads and Fitz-Hugh.<sup>1</sup> A case of this type has been admitted to the Pediatric Service of the University of Virginia Hospital five times between 1945 and 1948. In the first portion of this report an account of this case is presented and other similar reports in the literature are reviewed. The second portion of the paper deals with special studies made on our patient which have suggested a new approach to the therapeutic problem presented by patients of this type.

## PART I CASE REPORT

A 5 year old white female was admitted to the Pediatric Service of the University of Virginia Hospital first in November 1945 for study of abnormal bleeding which had occurred intermittently since the age of two weeks. Prior to admission episodes of severe epistaxis, hematemesis and melena had occurred but there was no history of hemarthrosis. On admission hematuria was present.

Developmental history revealed that the patient received an essentially adequate diet but developed somewhat slower than the average child. She experienced no illnesses other than whooping cough and chickenpox and received no salicylates or other toxic medications. A thorough investigation of other members of this family was not possible. No history of hemorrhagic phenomena in other members of previous generations could be elicited from the mother. The prothrombin conversion time of the mother's plasma was normal.

*Physical Examination.* On admission the patient's temperature, pulse and respirations were normal. There were many old hematomata of varying size over both lower extremities but there were no recent hemorrhages. There was no jaundice, adenopathy or hepatosplenomegaly.

*Laboratory Data.* Hematologic studies: red count 3.7 millions, hemoglobin 11 Gm., white count 7,200. Blood and bone marrow differential counts normal. Reticulocytes 1.3 per cent, hematocrit 39, sedimentation rate 6 mm. at the end of one hour. Platelets were 388,000, bleeding time was 2½ minutes (Duke), tourniquet test was negative and clot retraction was normal. The prothrombin time (Quick) ranged from 62 to 92 seconds and the clotting time (Lee White) 11 to 48 minutes on various admissions.

Admission urinalysis showed 3 plus albumin, innumerable red cells, no casts and specific gravity was high. Subsequent examinations were negative. Stool examination revealed *ascaris lumbricoides* ova on the first admission but none on subsequent observations. Blood urea was 20, calcium 9.4. The Schick, tuberculin, Wassermann and plasma salicylate tests were negative.

*Liver Function Studies (1945-1948 inclusive).* Bromsulfalein, hippuric acid excretion, cephalin flocculation, thymol turbidity, proteins and A/G ratio, alkaline phosphatase, cholesterol and esters, icterus index, bilirubin, urobilinogen quantitative 24 hour urine and urobilinogen quantitative fecal were all within normal limits.

*Other Studies (1945-1948 inclusive).* Electrophoretic study of the patient's blood revealed a normal protein pattern with no fibrinogen deficiency. Direct examination of nailbed capillaries revealed normal appearance and normal response to traumatic rupture. Roentgenograms of the chest, skull and long bones were normal.

Deficiency of vitamin K, liver dysfunction and depression of prothrombin by certain substances such as dicoumarol or salicylates were considered as possible causes of the prothrombin deficiency. The lack of

---

From the Department of Internal Medicine, University of Virginia Hospital, Charlottesville, Va.

response to large doses of synthetic vitamin K preparations given by oral and parenteral routes seemed to exclude vitamin K deficiency. A careful history examination and numerous tests of liver function failed to indicate liver disease or the presence of any agent known to depress prothrombin formation. Therefore it appeared that this patient had idiopathic hypoprothrombinemia. The absence of any change in either the subjective or objective clinical manifestations including signs of liver disease over a three year period of repeated observations has substantiated this interpretation.

In reviewing the literature on idiopathic hypoprothrombinemia, and the various cases reported therein, one is impressed with the definite disease pattern they seem to form. The onset is during infancy or childhood without any sexual predilection. The family history is frequently bisexually positive for hypoprothrombinemia of a subclinical degree. These patients run a similar chronic course, characterized by cutaneous hemorrhages, epistaxis, hematemesis, hematuria, hemarthrosis, and uterine bleeding severe enough to necessitate hysterectomy.<sup>3</sup> The results of the hemorrhagic tests in these patients are nearly uniform. Besides the prolonged prothrombin times, the clotting time was prolonged in all but the case of Murphy and Clark,<sup>2</sup> which presented more the picture of pseudohemophilia with prolonged and variable bleeding time and abnormal nailbed capillaries, but normal platelets and coagulation time. Though the cases of Rhoads and Fitz-Hugh,<sup>1</sup> and Hagen and Watson<sup>3</sup> showed prolonged bleeding times, these were noted to be only slightly or infrequently abnormal. In general the capillaries, platelets, and other factors have shown no abnormality. The prolonged coagulation time is presumably a reflection of the prothrombin defect, since no increase in circulating anticoagulants, antithrombin or similar substances have been demonstrated.

Successful therapeutic efforts in these cases have been limited to the administration of some effective factor, or factors, present in whole blood, plasma, or as in the authors' case, serum. These patients have been uniformly refractory to various forms of vitamin K administration.

Idiopathic hypoprothrombinemia is not always of a degree sufficient to produce clinical bleeding and several such subclinical cases have been reported. Many of these occurred in families who were studied when one member suffered clinical bleeding, as reported by Giordano,<sup>4</sup> Murphy and Clark,<sup>2</sup> Hauser,<sup>5</sup> and Hagen and Watson.<sup>3</sup> Other cases have been discovered by Plum<sup>6</sup> and Quick,<sup>7,8</sup> and have led the latter to speculate on the prevalence of this state. The prothrombin estimations of these patients ranged from three seconds above the controls to as little as 24 per cent of normal,<sup>4</sup> and in a few the coagulation times were slightly prolonged, but not of the order which those with an hemorrhagic disorder exhibited. The other hemorrhagic tests failed to indicate abnormalities in the other factors concerned in hemostasis, except for a few isolated observations unassociated with any abnormal bleeding.

period of treatment with vitamin K and blood Autopsy showed a granulomatous process, possibly Hodgkin's sarcoma, and probably hematogenous tuberculosis in the lungs, liver and nodes

In table 1 we have grouped the cases thus far reported in which there is a chronic hemorrhagic disorder associated with a defect in the prothrombin mechanism of undetermined etiology. Thus it can be seen that these cases present a very similar clinical picture and essentially the same laboratory abnormalities if the Quick<sup>1</sup> method of prothrombin determination is used. The various studies indicate that hypoprothrombinemia may not be a single simple defect and that perhaps more than one factor may be involved in deficient prothrombin conversion. Owren<sup>12a, b</sup> concluded that his patient was lacking in what he termed factor V, and chose to designate the resulting hemorrhagic state parahemophilia. Quick<sup>7</sup> studied two brothers with abnormal bleeding and concluded that there was no deficiency of prothrombin component B or the labile factor, but instead, a deficiency of a new coagulation constituent. He felt that pseudo-hypoprothrombinemia was a more fitting designation for this condition. Of course, the implication is that some of these reports are dealing with similar pathologic processes to which different terms or interpretations have been applied.

## PART II SPECIAL STUDIES

At the time of the first admission of our patient in 1945 certain preliminary observations were carried out in an attempt to determine the nature of the prothrombin defect. Because of the concept of Quick<sup>8</sup> and others<sup>16</sup> at that time that the prothrombin complex was composed of two factors, prothrombin A, which was labile and disappeared from stored plasma, and prothrombin B, which was depressed by dicoumarol, various mixtures of the patient's plasma with normal and old human and dicoumarinized dog plasma (human not available) were set up to determine which component was reduced in this patient. The results are shown in table 2. It will be noted that when stored plasma and dicoumarinized plasma, each with a long prothrombin time, were mixed in equal parts there was a marked reduction in the prothrombin time to a level far below that of either plasma alone. This could be interpreted as indicative of a different type of prothrombin deficiency in each type of plasma and that mixing the two restored the deficient parts of the prothrombin complex more nearly to normal. It was also apparent that the addition of either prothrombin deficient stored plasma or dicoumarinized plasma to the patient's plasma lowered the prothrombin time below that of either plasma alone. This might indicate that the patient was deficient in both of these factors.

An infusion of old plasma brought no appreciable change in the patient's prothrombin time. These data could be interpreted to mean that the patient's plasma was deficient in both prothrombin A and B.

At the time of the admission in 1948 the patient's coagulation defect was felt to be the same as that found on the previous admissions. Possible deficiency of vitamin K was again excluded by the intravenous administration of 75 mg of synthetic vitamin K. The prothrombin time was not affected by this substance, being 63 seconds before injection and 65 seconds 6-12 hours after injection.

The patient's prothrombin time was consistently elevated, ranging from 50 to 80 seconds. These values varied from day to day, despite fair uniformity of activity of the thromboplastin as tested against normal controls. No apparent reason for the wide variations could be found.

In the light of certain recent advances in the knowledge of factors concerned in coagulation, especially in regard to prothrombin conversion, it was felt that some preliminary investigations were indicated to determine the nature of the defect exhibited by this patient. The procedures previously carried out (table 2) involving

TABLE 3 — *Prothrombin Determinations on Mixtures of Different Types of Plasmas in Equal Volumes (1948).  
Prothrombin time in seconds*

Mixture of Dicoum. & Stored (21.5)	19.0	17.0		

mixing of various types of human plasma with the patient's plasma in equal volumes were repeated. The results are shown in table 3.

It was found, as previously, that normal plasma mixed with the patient's plasma in equal amounts substantially lowered the prothrombin time of the patient's plasma, but not to normal levels. Normal plasma mixed with either old plasma or dicoumarinized plasma gave about the same result. Both old plasma and dicoumarinized plasma, each with a prolonged prothrombin time, substantially lowered the patient's prothrombin time, but not as markedly as did normal plasma. Furthermore, it will be noted that a mixture of all three of these abnormal plasmas yielded a lower prothrombin time than any two.

These data could be interpreted as previously to indicate that the lower prothrombin times resulting from mixtures of the various prothrombin deficient plasmas was due to an elevation of the prothrombin concentration of the plasma mixture as a result of different portions of the prothrombin complex being supplied by the various individual plasmas. However, this interpretation, which is according to the concepts of Quick, is open to some objections. Against it is the fact that the addition of purified prothrombin\* to the patient's plasma failed to bring

\* Supplied through the courtesy of Dr. Walter H. Seegers, Wayne University College of Medicine, Detroit, Mich.

the prothrombin time to normal. Bringing the concentration of added prothrombin to 100 mg per 100 cc lowered the prothrombin time from 67 to 37 seconds. The additions of increasing amounts failed further to reduce the time of prothrombin conversion. This result would indicate a deficiency of some other factor necessary for the rapid conversion of prothrombin to thrombin as well as a deficiency of prothrombin per se. Mixing the various types of prothrombin-deficient plasmas may have altered the concentration of this factor and hence caused more rapid conversion of prothrombin, even though the latter was still in low concentration.

The existence of a factor in normal blood which is necessary for the rapid conversion of prothrombin seems to be beyond dispute. The disagreement as to the nature of the factor and its mechanism of action will not be discussed here. We have chosen to use the term accelerator or activator globulin (Ac-globulin) after Ware, Guest, and Seegers,<sup>17</sup> but are cognizant of the unsettled similarity of the substance so named to the labile factor of Quick,<sup>9</sup> factor V and factor VI of Owren,<sup>12a, b</sup> and the prothrombokinase of Milstone.<sup>18</sup>

Because of the importance of this Ac-globulin in the rate of prothrombin conversion it is apparent that the Quick one-stage prothrombin technic is not an accurate measure of prothrombin concentration in the plasma, since the variable factor of accelerator globulin activity is not controlled. The two stage determination<sup>19</sup> of prothrombin concentration would appear to be less affected by variations in accelerator globulin since the rate of conversion of prothrombin is not measured, but rather the actual amount of thrombin produced during a definite incubation period. However, this test may be criticized as a measure of prothrombin concentration since the activity of Ac-globulin apparently also influences the amount of thrombin produced.<sup>20</sup> Seegers, et al. have recently modified the two stage method to measure the concentration of prothrombin by adding known amounts of Ac-globulin to a reaction mixture containing specified amounts of thromboplastin, calcium ions and the plasma to be tested, and incubating for varying periods of time before adding fibrinogen. Although the Quick one stage method<sup>1</sup> does not measure actual prothrombin concentration, it does serve as an accurate measure of the speed of prothrombin conversion to thrombin, a reaction in which all of these factors take part. It will be noted that in the protocols presented, prothrombin is expressed in terms of prothrombin time rather than per cent concentration of normal. This terminology was used because it is evident that a measure of prothrombin time cannot be accurately interpolated to prothrombin concentration by the usual graphic method unless the activity of Ac-globulin is controlled.

Ware and Seegers have demonstrated<sup>20</sup> that accelerator globulin is in a highly active state as it exists in serum after clotting. They believe that it is in a less active state in the plasma where it exists as a proenzyme. According to these authors it is activated by the formation of small amounts of thrombin in the first stage of clotting, amounts too small to cause clotting of fibrinogen. The activation of plasma Ac-globulin is then followed by increased thrombin formation and the reactions proceed by co-autocatalysis. After the concentration of thrombin has been built up to the point where clotting occurs, the reaction is spent. The thrombin formed is destroyed, as is thromboplastin, but Ac-globulin was found to survive in the serum in a highly active state.

It was therefore felt that some estimation of the activity of accelerator globulin might be ascertained by studying the influence of small amounts of the various sera on the speed of prothrombin conversion of the various plasmas. It was considered that the small amounts of other factors pertaining to clotting in thrombin-free serum, such as antihemophilic globulin, platelet breakdown products, and prothrombin would not interfere with the use of serum as a rich source of this material. Platelet breakdown products and antihemophilic globulin appear to participate in the initiation of coagulation and furnish active thromboplastic effect. They have no influence on the rate of prothrombin conversion when an excess of artificial tissue thromboplastin is used, as shown by Ferguson and Lewis.<sup>21</sup> The prothrombin content of fresh serum immediately after clotting is normally less than 10 per cent of that of normal plasma. Barium carbonate adsorption of the residual prothrombin was carried out in some instances but difficulty was encountered in avoiding an excess of the material which inhibits the activity of prothrombin in the plasma to which the barium carbonate-treated serum was added. It was not felt that the small amount of prothrombin in the serum would be sufficient to bring about the striking changes noted.

TABLE 4—*The Effects of Various Sera on the Prothrombin Times of Various Types of Plasma (One Part Serum in Three Parts Plasma) Plasma Prothrombin Times in Seconds*

Types of sera added	Patient	Dicoumarinized	Stored
None	60.5	24.8	23.5
Normal serum	15.7	14.5	17.0
Patient's serum	48.5	19.5	16.5
Dicoumarinized serum	28.5	24.0	23.3
Stored serum	21.0	18.5	21.0

It will be seen from table 4 that one part of normal serum in three parts of the patient's plasma brought about a marked reduction in the prothrombin time from a value of 60.5 to 15.7 seconds (normal control 15.0 seconds). Normal serum also brought about a striking reduction in the prothrombin time of dicoumarinized and old plasma, particularly the former. On the other hand, the patient's serum did not bring about nearly so marked a reduction in the prothrombin time of either the patient's or dicoumarinized plasma, but did reduce that of old plasma, the reason for which is not apparent. Neither serum from dicoumarinized nor stored blood possessed as much accelerating effect as did normal serum. There seemed little doubt that normal serum possessed a factor which was capable of accelerating prothrombin conversion in the patient's plasma. It is apparent that any alteration in prothrombin concentration by the addition of serum could not account for this remarkable reduction in prothrombin time (table 3). This acceleratory effect of normal serum on prothrombin conversion is also demonstrated by the use of purified prothrombin. A clotting mixture consisting of purified prothrombin 0.1 cc., human fibrinogen 0.2 cc., and thromboplastin 0.05 cc. was used. Upon recalcification with 0.1 cc. calcium chloride (0.024 M) at 37°C it was observed that purified prothrombin was converted to yield sufficient thrombin to clot human fibrinogen in an average

time of 286 seconds. This is in accord with previous findings that thrombin is produced slowly, in the absence of Ac-globulin by the interaction of thromboplastin, calcium and purified prothrombin.<sup>2</sup> However, if 0.05 cc. normal serum (thrombin-free) was added to the mixture at the time of recalcification with 0.05 cc. calcium chloride, clotting occurred in 45 seconds. Also it was noted that fresh normal serum possessed a more marked acceleratory effect than did normal serum which was 24 to 48 hours old, the latter bringing about clotting in 74 seconds. In contrast, using the same technic, fresh serum from the patient produced clotting in 90 seconds and 24 hour old serum in 110 seconds.

The data in table 5 show the relative potency of fresh normal serum in accelerating the conversion of prothrombin in the patient's plasma. These findings would be in accord with the concept of the enzymic or catalytic action of this substance.

A modification of the two stage method of prothrombin determination was performed in order to evaluate further the concentration of prothrombin in this patient's blood. The results of this test seemed to indicate an actual deficiency of prothrombin, as well as delay in its convertibility to thrombin, as previously demonstrated. A 1:11 dilution of control defibrinated plasma yielded a prothrombin time of 13 seconds whereas the same dilution of the patient's defibrinated plasma yielded a prothrombin time of 68.5 seconds. However, since adequate control of

TABLE 5—*The Effect on the Prothrombin Time of the Patient's Plasma of Serum Added to Increasing Amounts of Plasma*

Proportions of serum to plasma	1:1	1:3	1:6	1:12	1:20	1:40	1:80	0:1
Prothrombin time in seconds	16	16.5	18	22	25.5	31.5	39	57

accelerator globulin activity was not possible, interpretation of the results was difficult. Dr. Walter Seegers kindly performed determinations of both prothrombin and Ac-globulin of a sample of the patient's plasma. He reported a prothrombin concentration of 41 per cent by the original two stage technic and 60 per cent by the modified technic in which the amount of accelerator globulin was controlled. He concluded that the Ac-globulin concentration was in the neighborhood of 50 to 60 per cent of normal. It is interesting to note that neither the prothrombin concentration nor that of Ac-globulin, as determined by Dr. Seegers, was as low as might have been anticipated. Perhaps the moderate depression of both these factors simultaneously was sufficient to bring about the marked retardation of prothrombin conversion noted, whereas a deficiency of either factor alone would have to be more extreme before a comparable delay in prothrombin conversion time would be noted. Although Dr. Seegers' prothrombin value was somewhat higher than our tests would seem to indicate, his general conclusions, that a deficiency of both factors was present, are in agreement with the results we obtained.

The marked acceleration of prothrombin conversion in the patient's plasma by the addition of normal serum in vitro prompted the administration of fresh normal serum to the patient in the hope of lowering the prothrombin time of the circulating blood. Accordingly a normal donor of the same blood type was bled. The

blood was allowed to clot and the serum removed under sterile precautions. Fifteen cc of this serum was injected intravenously 2 hours after collection, at which time it was free of thrombic activity. There was a slow decline in the patient's prothrombin time from a level of 67 seconds to 37 seconds in 16½ hours. At this time 45 cc more of the serum (which was by this time 18 hours old) was given and the prothrombin time fell from 34 seconds to 25 seconds in one hour. Three hours after the second injection the patient's prothrombin time was 22 seconds. This was the lowest prothrombin time yet recorded for this patient. Twenty-four hours later the patient's prothrombin time was 32 seconds. It is of interest that as little as 15 cc of serum given intravenously had a significant effect. These results are shown graphically in figure 1.

FIG 1 —The effects of intravenous administration of fresh serum on the prothrombin time of patient H H

It is interesting to note that the patient's coagulation time, which was 19 minutes on admission, was now 12 minutes, suggesting an improved state of coagulability of the patient's blood. It is also of some interest that the patient's serum became more active in accelerating prothrombin conversion when added to her own plasma after the above treatment. Thus, one part of the patient's serum obtained after treatment, with three parts of the patient's plasma collected before the intravenous administration of serum, lowered the prothrombin time from 64 seconds to 27 seconds, whereas previously the patient's serum had reduced the prothrombin time from 60.5 seconds to 48.5 seconds.

The patient was seen March 15, 1949 on a return visit after the preceding data had been completed. She was admitted to the hospital because of bleeding from her gums for three weeks. Examination revealed six carious deciduous teeth. The

gingival tissue around some of these was hypertrophied and irritated and bleeding occurred with mastication. Prothrombin time (Quick) was 72 seconds with a control of 12, and the clotting time (Lee White) was 23 minutes. There were no other significant changes from the previous studies.

In figure 2 are shown the effects of giving the patient fresh whole blood and fresh serum, both separately and, later, together. After each administration it will be noted that the prothrombin and clotting times were markedly reduced within an hour's time and further, that the most marked reduction was obtained when the two were given close together, near the end of her stay. These results are interpreted as further evidence in support of the hypothesis that she is deficient

Fig. 2. The effects of fresh blood and serum on the prothrombin and clotting times of patient H. H.

in two factors, prothrombin and accelerator globulin, which were presumably supplied by the blood and serum respectively.

The extraction of the six carious teeth was done under a general anesthetic and bleeding was minimal both in amount and duration. Her course remained uneventful and it was felt that she had been carried through a potentially dangerous procedure by the use of the blood and serum.

### Discussion

These studies support the concept that serum contains an active substance which is capable of accelerating prothrombin conversion to thrombin. It is likely that deficiency of this substance may play a role in many types of hemorrhagic states as suggested by Alexander and co-workers.<sup>23</sup> It is probable that alterations in

Ac-globulin are of particular importance in various types of prothrombin deficiency. Further investigation is needed to delineate clearly the different types of hypoprothrombinemia and to evaluate the use of serum in treating certain cases of this type.

Our observations also suggest, as do those of Owen and Bollman<sup>14</sup> in dogs, that depression of Ac-globulin activity is a major factor in the hypoprothrombinemia produced by dicoumarol. It is obvious that if such be the case, serum or some fraction of the serum such as Ac-globulin may be of potential value in quickly reducing the prothrombin time to safe levels in cases of dicoumarol intoxication. We have carried out preliminary observations on the effect of intravenous normal serum from compatible blood on the prothrombin time of three patients receiving dicoumarol. The pattern of response in all has been the same. In the most recent patient the prothrombin time before giving 175 cc. of serum was 49 seconds. An hour after administration of the serum it was 30 seconds, rising to 38 seconds at the sixth hour, with controls of 15. Twenty-four hours later it had risen to 40 against a control of 12 seconds.

From the evidence that both prothrombin and Ac-globulin are depressed in hypoprothrombinemia following dicoumarol and with liver disease<sup>10a, 15</sup> control of the coagulation defect will depend upon the correction of both deficiencies. An apparently effective and simple means of so doing is to give whole blood, thus supplying prothrombin and fresh, thrombin-free serum rich in Ac-globulin in a highly active form.

#### SUMMARY AND CONCLUSIONS

1. The reported cases of idiopathic hypoprothrombinemia are reviewed briefly, and a case observed for over three years is presented. Particular attention is called to the similar clinical pattern presented by the chronic cases.

2. Studies are presented indicating that in this patient the delay in prothrombin time was due, at least in part, to a deficiency of a factor necessary for rapid conversion of prothrombin. This factor, or factors, which we have called Ac-globulin, is contained in a highly active state in fresh normal serum.

3. After the *in vitro* demonstration of a deficiency of Ac-globulin in the patient's blood, it was possible to bring about a marked reduction in the patient's prothrombin time by the intravenous administration of relatively small amounts (15 to 45 cc.) of fresh normal (thrombin-free) serum. A further reduction of the prothrombin time to near normal values was brought about by combined whole blood and serum administration. The evidence suggests that partial correction of both prothrombin and Ac-globulin deficiency respectively resulted from such therapy.

4. The possible effects of serum and whole blood upon the delayed prothrombin conversion rate of dicoumarolization and liver disease are discussed and preliminary observations in the former type suggest that such therapy may be useful.

# THE EFFECT OF ARTIFICIAL SURFACES ON BLOOD COAGULABILITY, WITH SPECIAL REFERENCE TO POLYETHYLENE

By THOMAS J. DONOVAN, M D , AND BERNARD ZIMMERMANN, M D

## INTRODUCTION

AS A PRELIMINARY evaluation of the efficacy of polyethylene tubes in reparative vascular surgery, comparative studies were carried out on the coagulability of blood in tubes of polyethylene and other nonvascular materials. Polyethylene is a plastic made by polymerizing ethylene under heat and pressure to hydrocarbon chains somewhat longer than those of paraffin. This may be represented as follows:

This plastic should be well tolerated in body tissues, since synthetic plastics of the simplest monomeric structures are known to cause the least reaction. This was established by Ingraham et al., who found that small pieces of polyethylene implanted in the cerebral cortex of dogs, cats, rabbits and monkeys caused only slight glial thickening with no significant foreign body reaction, up to three months postoperatively.<sup>10</sup> They stressed, however, the importance of using *pure* polyethylene, because any traces of the antioxidants used commercially to increase its insulating properties have given progressive fibrosis and marked foreign body reaction.

The effect of a pure polyethylene surface on blood clotting was investigated in two ways. First, a series of clotting times was performed in tubes of polyethylene, glass, paraffin and collodion. Secondly, the capillary action in polyethylene and glass tubes was studied in an attempt to explain the increased coagulation time in polyethylene tubes.

## MATERIALS AND METHODS

*Effect of polyethylene on tissue.* Inasmuch as the purity of the polyethylene\* is an important factor in the coagulation studies, small pieces of polyethylene and lucite were inserted subcutaneously in the backs of 30 rats and the surrounding tissue removed *en bloc* for histologic study at various intervals. Polyethylene was found to cause the same degree of fibrosis as lucite, a plastic which has been shown to be tolerated relatively well in animal and human tissues. The thin fibrous sheath surrounding the plastic was seen to increase slightly during the first three months. Figure 1 shows the reaction to polyethylene and lucite at three months. The fibrous

capsule surrounding the space from which the plastic was removed at fixation showed no foreign body giant cells or leukocytes under higher magnification.

*Measurement of coagula in time.* Glass tubes of 5 mm i.d. were bent in the form of a semicircle of 6 cm radius as nearly identical geometrically with a polyethylene tube as it was possible to make them. Some of the glass tubes were lined with a thin layer of paraffin by filling them with hot liquid paraffin for a moment, emptying the tubes and placing them in a cold water bath for a few seconds. Other glass tubes were lined with a collodion film which was allowed to dry for eighteen hours. Four tubes, one each of glass, paraffin, collodion and polyethylene were

FIG. 1—THE TISSUE REACTION TO POLYETHYLENE (A) AND LUCITE (B) THREE MONTHS AFTER SUBCUTANEOUS INSERTION INTO RATS

The fibrous capsule surrounds the space from which the plastics were removed during fixation. The width of each piece of plastic represented by the diameter of the capsule was about 2 mm while the length approximated 1 cm.

inserted in a rack. Venepunctures were performed on healthy dogs using an 18 B-D needle attached to a 10 cc syringe lined with liquid petrolatum. Ten cc of blood were allowed to flow into the syringe with exclusion of air, the needle was removed, and a little over 2 cc of the sample was transferred carefully into each of the four tubes. The time was noted by stop watch when the first definite fibrin precipitate became perceptible in each tube on moving the rack. The temperature was kept relatively constant at  $20^{\circ}\text{C} \pm 5$  degrees in an air-conditioned room. In the first groups of clotting times, the rack was moved every thirty seconds until the

\* When any difficulty with the venepuncture was encountered the blood was discarded and the procedure repeated.

last tube clotted. In this way each tube was moved uniformly and each group of four observations was comparable to the other fourteen in extent of motion of the blood in the tube. In the last fifteen groups of clotting times the rack was moved at three minutes and at decreasing intervals thereafter as the end points were approached. Thus, the motion of the blood was reduced and the clotting times for each surface were somewhat lengthened. The first fibrin precipitation was used as an end point because it marks the beginning of the second phase of coagulation, i.e., fibrinogen conversion to fibrin. It has been re-emphasized by Nygaard that either this end point or complete clotting is suitable since the first phase of coagulation, i.e., prothrombin conversion to thrombin, is proportional in duration to the second phase.<sup>16</sup> In tubes of various materials complete clotting may be less clearly defined, as an end point, than the initial appearance of fibrin.

*Measurement of surface action.* The amount of adhesive force exerted by the surfaces of glass and polyethylene on water was measured by suspending various sized capillary tubes\* of glass and polyethylene in clean graduates half filled with distilled water in an air-conditioned room maintained at  $25^{\circ}\text{C} \pm 2$  degrees. The differences between the water level in the capillary tube and the graduate were measured by a cathetometer. These measurements were repeated at lengthening intervals until the difference in water levels became constant. In glass tubes such constancy was obtained in minutes, while with polyethylene tubes in the initially dry state the final level was reached in one to two weeks. Since the delay in obtaining a constant level is undesirable, some of the polyethylene tubes were soaked in distilled water for periods up to two and one-half months prior to the determination of their capillary action. This served to increase markedly the initial and final wettability of the polyethylene tubes, and hence the height of the fluid levels, but did not hasten the attainment of a final constant level.

The capillary action of polyethylene and glass tubes was also measured using canine plasma in place of distilled water. Harkins and Brown and other workers have found that organic, viscous liquids of alkaline reaction give exceptionally low surface tension values and are unsuitable for capillary action studies.<sup>7</sup> The values obtained for polyethylene and glass tubes in plasma were markedly low, as would be predicted, but were roughly proportional to those determined for polyethylene and glass using distilled water.

The radius of each tube was determined by filling a carefully measured length of the tube with pure mercury, which was then weighed. From the radius and the distance water is repelled or attracted, a negative or positive value, respectively, for the adhesive force between the surface and water was obtained by the equation

$$T (\text{attractive force in Gm/cm}) = \frac{\text{height} \times \text{density} \times \text{radius}}{2} \quad (1)$$

## RESULTS

*Effect of surface on blood coagulation.* The mean values of the 30 clotting times for each surface studied are shown in table 1, in which they are compared with a

\* Tubes were chosen having a cylindrical bore of about 0.05 cm radius which did not vary significantly in any part of the tube.

similar series reported by Hirschboeck in a comparison of lucite, glass and paraffin.<sup>8</sup> Hirschboeck's clotting times were all longer than those of the present series, because he used as his end point complete clotting instead of the first fibrin deposition. He also used human blood in tubes twice the diameter of ours. Canine blood has been shown to have a greater prothrombin conversion rate than human blood.<sup>11</sup> The differences between the clotting times in glass and paraffin, glass and the plastic tested, and between paraffin and the plastic tested are statistically significant in both series.

These data show that the clotting time in a polyethylene tube is about twice as long as in a glass tube and almost as long as in tubes lined with paraffin or collodion. Comparison of this series with that of Hirschboeck shows that the effect of polyethylene and lucite surfaces in delaying coagulation are very nearly the same and are not greatly inferior to those of paraffin and collodion, which simulate vascular endothelium in this respect as well as any known surface.

Clot retraction was observed repeatedly following the coagulation studies, and although there was some variation, the collodion surface was exceptional for the

TABLE 1.—The Coagulation Times (Minutes) of Blood in Contact with Various Surfaces

absence or slight degree of clot retraction. In the paraffin glass and polyethylene tubes retraction was present to a moderate and essentially similar degree.

**Effect of surface on capillary action.** In glass tubes of .056 cm. and .053 cm. radius the water levels were stabilized immediately at heights of 2.62 cm. and 2.73 cm., respectively. These figures substituted in the equation give positive values (uncorrected for meniscus) of 0.073 and 0.072 Gm./cm., respectively, for the attractive force of glass on water at 25°C. These agree well with the value of 0.0736 Gm./cm. at 25°C. calculated from the surface tension value for water at 20°C. established by Harkins and Brown<sup>7</sup> and other workers using the capillary height method. Hirschboeck reported a value of .053 Gm./cm. for the force of adhesion of water in glass in a comparison of the capillary effect in tubes of glass, lucite, paraffin, and collodion.<sup>8,9</sup> No details were presented concerning his methods, but the figure is exceptionally low as compared with the well-established standard value mentioned above.<sup>7</sup>

Figure 2 shows typical capillary action curves for measurements in two different sizes of polyethylene tubes starting from an initially dry state. The polyethylene originally repels water markedly, nearly to the extent reported by Hirschboeck for paraffin.<sup>8</sup> Over a period of days, however, the levels rise at a diminishing rate

and flatten out in about a week. Calculations based on the final levels observed for the two sizes of polyethylene tubes give a value of 0.34 Gm/cm for the attractive force of polyethylene on water at 25 C, slightly under half the above-mentioned value established for glass.

Table 2 shows the values for surface force in polyethylene and glass tubes as compared with the Hirschboeck values for glass, lucite, paraffin, and collodion<sup>6</sup> and the standard value for glass.<sup>7</sup> The maximum attraction of polyethylene for

water as determined above is about half that of glass and slightly less than that reported for lucite. Initially it repels water nearly as much as paraffin.\*

Lampert has stated that the effect of a surface on the coagulation time of blood is inversely proportional to its wettability.<sup>7</sup> Comparison of the data in table 2

\* The application of the capillary height method to surface tension measurements may be considered to be of somewhat doubtful value in systems of liquids which do not wet glass; hence as in these experiments of water against unwettable polyethylene. The angle of contact may safely be assumed to be zero for water against glass, but the same is not true for the plastic systems under consideration. Although no correction has been made for this factor and the values are accordingly not offered as being absolutely correct, they serve the purpose of this work adequately.

with those in table 1 shows that polyethylene follows Lampert's rule, as do lucite, paraffin, and glass with collodion as an exception

### Discussion

The process that determines the speed and extent of coagulation under normal circumstances is the conversion rate of prothrombin to thrombin, which is in turn dependent on the amount of active thromboplastin present. Thromboplastin is released outside of the blood stream from tissue juices and within the vascular system by the breakdown of platelets. Indirect and debatable evidence suggests that thromboplastin is normally present in the circulating blood, but is rendered inactive by combination with an antithromboplastic substance, and that the balance between the concentrations of these substances determines the balance between coagulability and fluidity of the circulating blood.<sup>17, 5, 4, 3, 12, 8, 11, 1</sup>

✓ Surfaces that repel water, such as paraffin and some of the plastics, tend to inhibit the agglutination and disintegration of platelets and the subsequent liberation of thromboplastin.<sup>18</sup> Since the extent of clot retraction is normal in polyethylene tubes, this material, in contrast with collodion surfaces, presumably has no increased affinity for fibrin. Furthermore, polyethylene repels water relatively well and therefore probably inhibits platelet agglutination and lysis in the same manner described by Quick for paraffin and other water repelling surfaces.<sup>16</sup>

The mechanism by which water repelling surfaces delay coagulation, however, may not be concerned solely with platelet disintegration. Lozner and Taylor and others describe a catalytic action of foreign surfaces on the clotting of cell-free recalcified plasma.<sup>11</sup> Tocantins postulates that the increased coagulability of cell-free plasma after exposure to glass is due either to an activation of thromboplastin or an inactivation of antithromboplastin.<sup>17</sup> He cites the work of Gortner and Briggs who reported a negative charge on a glass surface which disappeared when the glass was lined with paraffin.<sup>4</sup> Electrostatic absorption of positively charged colloids was suggested by the latter as a possible mechanism in the initiation of the clotting of blood in contact with glass.

✓ The coagulation time is nearly as long in polyethylene tubes as in tubes lined with paraffin. Polyethylene's chemical structure, clot retraction, and repelling action on water are also similar to those of paraffin. It is therefore suggestive that it delays coagulation in a similar manner, i.e., by its relative inertness to the clotting colloids of blood as well as through its protective action on the stability of platelets.

### SUMMARY AND CONCLUSIONS

1. The reaction to small pieces of polyethylene and lucite in the subcutaneous tissues of 30 rats was studied at intervals up to three months after insertion. Polyethylene was shown to compare favorably in respect to minimum tissue reaction, with the well-tolerated lucite.

2. A series of clotting times was performed in polyethylene, paraffin, collodion and glass tubes. The clotting time in polyethylene tubes was about twice as long as in glass, and nearly as long as in paraffin and collodion-lined tubes. These data are similar to Hirschboeck's findings for lucite tubes.

3 Clot retraction was found to be moderate and essentially similar in polyethylene, paraffin, and glass tubes. It was slight or absent in collodion tubes.

4 Capillary tubes of polyethylene were shown to repel water initially and then gradually to attract water over a period of days to a maximum height about one half of that in glass tubes. Thus polyethylene follows Lampert's rule, which states that the effect of a surface in delaying the coagulation of blood is proportional to the capacity of that surface for repelling water.

# THE ROLE OF STAPHYLOCOAGULASE IN BLOOD COAGULATION

## II COAGULATION IN THE ABSENCE OF CALCIUM AND IN THE PRESENCE OF FLUORIDES, HEPARIN, AND AZO DYES

By JOHN B MIALT, M D

IN A preceding report<sup>6</sup> it was shown that broth cultures of staphylococci produce a substance (*staphylocoagulase*) which is able to clot plasma by reacting with a globulin substance (*coagulase globulin* CG) to form a thrombin-like substance (*coagulase-thrombin*, CT). Staphylocoagulase is not capable of clotting highly purified fibrinogen unless this reaction takes place, and the rate of production of CT when plotted gives a hyperbolic curve similar to that obtained in the activation of classic prothrombin to thrombin.

This similarity in the two reactions, plus the finding that in both cases the final product is one which clots highly purified fibrinogen, naturally leads to investigations aimed at establishing whether the two reactions are the same, similar, or unrelated. This report presents studies of the reaction of Staphylocoagulase with CG to form CT as influenced by factors known to have an effect on the conversion of prothrombin to thrombin and on the activity of thrombin.

### I *The Role of Calcium in the Staphylocoagulase Reaction*

It has long been known that the presence of oxalates or citrates does not interfere with the coagulation of plasma by staphylococci.<sup>15-17</sup> However, in the absence of quantitative studies it has been impossible to state that the presence of calcium ions is not necessary for the staphylocoagulase reaction. Because of the important role of calcium in the conversion of prothrombin to thrombin, a study of this factor in the staphylocoagulase reaction has been undertaken.

The method used was that of progressive removal of calcium by controlled molar concentrations of oxalate. Blood (human) was drawn into a Silicone\* coated syringe, and all the apparatus used in this section was similarly coated. Plasma was obtained by centrifugation and then diluted 1:10 with physiologic saline. The calcium concentration of the various reagents was determined by the method of Clark and Collip.<sup>8</sup> This made possible the addition of sodium oxalate in increasing molar concentrations beginning with a molar oxalate concentration just equal to the determined molar calcium concentrations and increasing to five times the calculated calcium equivalent.

Typical results are shown in table 1. It is obvious that progressive removal of calcium in no way interferes with the coagulation of plasma by either staphylocoagulase or CT, even when the plasma is otherwise incoagulable by an excess of thromboplastin. It seems justified to conclude that the reaction of staphylo-

This study was supported in part by a grant from the Marshfield Clinic Research Foundation.

\* General Electric Co. Dri-Film #9987

coagulase with CG does not need the presence of calcium ions, differing therefore in a very basic way from the activation of prothrombin. On the other hand, once CT is formed calcium is no longer required, a condition also applicable to the action of thrombin.

## II Coagulant Action of Staphylocoagulase and CT in the Presence of Soluble Fluorides

The anticoagulant action of the soluble fluorides is due to their decalcifying action plus the apparent adsorption of prothrombin.<sup>2</sup> Table 2 shows that sodium fluoride even in very high concentrations has no effect on the coagulation of plasma by either staphylocoagulase or CT. The failure of fluorated plasma to clot on addition of thromboplastin plus adequate amounts of calcium chloride supports the opinion that fluorides also remove a substance necessary for coagulation, and this is substantiated by the more marked deficiency of clotting on simple recalcification.

TABLE 1—The Effect of Progressive Removal of Calcium on the Coagulation of Plasma by Staphylocoagulase and by CT

Molar Ratio Ca Oxalate	Clotting time with Staphylocoagulase <sup>1</sup>	Clotting time with CT <sup>2</sup>	Thrombin Time <sup>3</sup>	Clotting time with Thromboplastin <sup>4</sup>
1 0	45'	10'	15 3"	45"

<sup>3</sup> Thrombin (Upjohn) diluted with saline

<sup>4</sup> Thromboplastin (Difco).

It is noteworthy, therefore, that the effect of staphylocoagulase is not inhibited by this deficiency. If fresh oxalated plasma is treated with a suspension of CaF<sub>2</sub> it can thereafter not be clotted either by recalcification or by recalcification with an excess of thromboplastin added, suggesting that prothrombin is the substance removed.

## III Coagulant Action of Staphylocoagulase and CT in the Presence of Heparin

The anticoagulant action of heparin has been thoroughly investigated,<sup>4, 6</sup> and its use in this study is indicated by its inhibitory effect on prothrombin activation and its antithrombotic action in the presence of an accessory plasma factor. Therefore it seemed important to determine whether it inhibits the staphylocoagulase reaction or the action of CT.

Table 3 shows the results of various coagulation tests on plasma containing increasing amounts of heparin. No inhibitory effect on staphylocoagulase can be

demonstrated, nor is there any evidence of inhibition of the CT effect. At the same time a definite inhibition of prothrombin activation is demonstrated, as well as a

clear cut antithrombic action, less striking in this case because of the use of diluted plasma for the experiments outlined

#### IV Coagulant Action of Staphylocoagulase and CT in the Presence of Azo Dyes

The anticoagulant action of certain azo dyes *in vivo* and *in vitro*<sup>16, 4</sup> has been attributed to the inhibition of thromboplastin<sup>16a, 17, 18</sup> or of thrombin.<sup>16</sup> Table 4 illustrates the anticoagulant effects of one of these dyes, Chlorazol Fast Pink, on plasma and also shows that there is no inhibition of either staphylocoagulase or CT. The anticoagulant action on plasma is very similar to that of heparin. In addition, the type of clots obtained with thrombin on plasma containing 2.0

and 5.0 mg/cc of dye suggests that there may be some stabilizing effect on fibrinogen as well, an effect attributed to the chemically related compound Germanin<sup>19, 25</sup>. It is interesting that the anticoagulant azo dyes, heparin, and Germanin contain ester sulfuric groups.

#### DISCUSSION

Following the demonstration by Arthus and Pagès<sup>1</sup> that the removal of calcium prevented the coagulation of blood, and the work of Pekelharing<sup>21, 22</sup> and Hammarsten<sup>18</sup> showing that it is essential for the formation of thrombin but not for thrombin activity, calcium has occupied a secure place in the classic scheme of blood coagulation.<sup>11, 23</sup> It is generally agreed that it is necessary for the activation

of prothrombin, probably through the formation of an intermediary complex<sup>12</sup>. Therefore since staphylocoagulase is active in the absence of calcium, we may suppose that its reaction with plasma does not involve the activation of plasma prothrombin. This conclusion is supported by the failure of heparin to inhibit the reaction in spite of its otherwise strong antiprothrombic effect, as well as the unreduced activity of staphylocoagulase in the presence of the other anticoagulants.

The failure of heparin and the azo dyes to inhibit the coagulation of plasma by CT suggests that the substance resulting from the reaction of staphylocoagulase and CG is not thrombin although it can be classified as thrombin-like. The nature of CT is not yet apparent, although it seems proper tentatively to place it in the group of substances which attack fibrinogen directly without the intervention of classic prothrombin and thrombin. Since we have consistently failed to demonstrate any fibrinolytic or fibrinogenolytic activity of the materials in the staphylocoagulase reaction it would appear justified tentatively to exclude it from the tryptic enzyme class. The inhibitory effect of heparin on tryptases<sup>14</sup> but not on staphylocoagulase would also support this tentative conclusion, as would the failure of fluorides to inhibit, the relatively wide pH range of activity, and other properties.<sup>20</sup> Obviously this and other points need further clarification. It is significant however that none of the other substances which are able to clot fibrinogen<sup>6, 7, 9, 10, 12</sup> have so far been demonstrated to need a globulin co-factor of the type involved in the staphylocoagulase reaction.

### CONCLUSIONS

1. The coagulation of plasma by staphylocoagulase and by CT does not require the presence of calcium.
2. The activity of staphylocoagulase and CT is not inhibited by soluble fluorides, heparin, or azo dyes.
3. The failure of antiprothrombic and antithrombic agents to inhibit the staphylocoagulase reaction indicates that it is not related to the activity of prothrombin.

# THE DETERMINATION OF THE LEVEL OF LEUKOCYTES IN THE BLOOD STREAM WITH INFLAMMATION: A THERMOSTABLE COMPONENT CONCERNED IN THE MECHANISM OF LEUKOCYTOSIS

By VALY MENAÏN, M.D.

*With the technical assistance of RUTH LEWIN AND LOUISE PIROVANE*

WITH AN acute inflammation the level of white cells in the circulation is altered, but it is difficult to predict the direction of the shift. There either may be an increase or a decrease in the number of circulating leukocytes, on the other hand there may be no appreciable change. The rise is in part due to the liberation by cells, severely injured at the site of an acute inflammation, of a specific type of alpha globulins\* termed as an entity, the leukocytosis-promoting factor (LPF).<sup>1-3</sup> Subsequent work has revealed that the active principle responsible for the effect of the LPF seems to be a polypeptide.<sup>4</sup> The rise in the number of white blood cells accompanying an inflammation cannot always be duplicated in magnitude by a single injection of the LPF. It is true that the constant production of the factor at the site of an acute inflammation may in part explain the level rising at times far above that obtained by merely injecting one dose of the LPF. On the other hand, it is conceivable that there may be other factors involved to explain the ultimate effect on the leukocyte level accompanying an acute inflammation.

Earlier studies have revealed that subsequent to the injection of the whole cuglobulin of an exudate, there often develops a leukocytosis.<sup>5</sup> At the time, it was surmised that necrosin associated with the cuglobulin fraction of an usually acid exudate by inducing tissue injury, in turn causes the local release of the leukocytosis-promoting factor with the eventual effect noticed.<sup>5</sup> This proved, however, to be an incorrect interpretation, for when necrosin was eliminated from the cuglobulin fraction, the noninjurious pyrexin or the pyrogenic factor of exudates still displayed the subsequent leukocytosis.<sup>6</sup>

The purpose of the present paper is twofold. In the first place, it will be shown that besides the thermolabile LPF of exudates,<sup>1</sup> there is also present a thermostable component, especially in acid exudates, which aids in explaining the mechanism of the final leukocytosis with inflammation. In the second place, an attempt will be made to point out the various factors concerned in the determination of the white blood cell level when there is a concomitant acute inflammation. It will be shown that the final picture is a resultant of the effect of the various factors previously described,<sup>7</sup> as well as the effect of the present component.

From the Agnes Barr Chase Foundation for Cancer Research, Temple University School of Medicine, Philadelphia, Penna.

Aided in part by a grant from the National Advisory Cancer Council. This is number 41 of a series entitled "Studies on Inflammation."

\* At least it seems to be associated with these proteins.

## METHODS

Dogs were given an acute pleural inflammation either with turpentine or with 5 per cent croton oil in olive oil. The amounts injected in the right chest cavity were either 1 to 1.5 cc. of turpentine or in one instance 0.3 cc. of 5 per cent croton oil in olive oil. On the following day and on subsequent days white blood counts were taken. The animals were tapped for the presence of any pleural exudate. The pH of the exudative material was measured by means of a Beckman pH Meter. The measurements were also checked by the use of Hydrion paper as a colorimetric measurement of the pH. Five to 1 cc. or even less was injected into the heart of a normal animal in which the basal white blood count had already been established. The number of circulating leukocytes was measured at hourly intervals for a period ranging from four to six hours. Into another dog a similar experiment was run in like manner, the only difference being that the injected exudative sample was either brought to a boil or boiled for thirty minutes. In this way any heat stable factor present in the exudative material could be recovered and its activity on the number of circulating leukocytes established. Since the primary activity, as it will be pointed out presently, of a heat stable component of the leukocytosis promoting factor seems to be located in exudates of an acid pH, this suggested that the effect may be associated with pyrexin, as indicated in earlier studies.<sup>6</sup> For this reason pyrexin was administered to normal dogs. These animals were observed at periodic intervals and as stated previously they eventually developed a marked leukocytosis in the blood stream.<sup>6</sup> This rise in the number of circulating leukocytes was observed to occur both in the systemic and the peripheral circulations, so that the effect could not very well be explained as a circulatory redistribution of white cells. Animals were also injected with boiled pyrexin in order to determine the heat stability of the leukocytosis-promoting component studied. In both experiments a differential count was made at the same time the absolute white cell level was determined. Particular care was given to establishing the percentage of immature or one lobe form of granulocytes as early as one hour after the administration of either boiled exudate or of boiled pyrexin. The reason for this step was to obviate the possibility of secondary injury in tissue caused by either exudate or pyrexin with subsequent formation of the LPF.

Finally, in an effort to determine whether the results obtained were specific for one species only, a similar type of experiment with whole and boiled guinea pig exudate was repeated on guinea pigs. The injection of guinea pig serum was utilized as a control in this series of experiments. Differential leukocytic studies were also undertaken. This study on dogs and on guinea pigs allowed a greater latitude in drawing final conclusions.

## RESULTS

When an acute inflammatory process is induced in the right pleural cavity, exudative material is often recovered and the pH of the exudate tends to be at an alkaline pH.<sup>8</sup> At times, however, the pH of the exudate may reveal a relatively neutral pH. On subsequent days the pH tends to be relatively at an acid pH.<sup>8</sup> When the pH of the exudate is alkaline or relatively neutral, it is found that the corresponding leukocyte level in the blood stream is either markedly increased, not significantly changed, or merely slightly increased. In some cases there is even a decrease in the level of circulating leukocytes. Such a decrease is likely to occur if the basal white blood cell count tends to be elevated. In other words, it is impossible to predict with any sense of precision what the injection of an irritant in the pleural cavity will do to the white cell count in the blood stream. Such data is assembled in table 1. On subsequent days the exudate recovered from such an acutely inflamed area tends to be at an acid pH,<sup>8</sup> and, generally speaking, the level of circulating leukocytes tends to be at a high level. This is illustrated in table 2. The question which immediately is raised is whether there is any single factor or a combination of factors which determine the ultimate picture in the level of leukocytes in the circulation with a concomitant acute inflammation.

If one groups all the exudative samples recovered in accordance with their hydrogen ion concentration, it is found that the final results are somewhat different in nature. These data are collected in table 3. It is readily seen that the most effective exudates in inducing a rise in the white blood cell count in a period from four

similar to the one encountered in case of unheated acid exudate (cf. table 3 and table 4). It would seem as if there is present a thermostable factor in acid exudates which tends to be either absent or present in reduced amounts in alkaline or neutral

FIG. 1.—THE EFFECT OF AN ALKALINE EXUDATE ON THE NUMBER OF CIRCULATING LEUKOCYTES IN AN OTHERWISE NORMAL DOG —●— The effect of an exudate of pH 7.55 ○---○--- The effect of boiling this same exudate. Note that the effect on the absolute white count is abolished but that there is still an effect on the percentage of discharged immature granulocytes in the circulation. This is indicated by the unstained columns, whereas the black columns indicate the effect of an untreated alkaline exudate on the percentage of immature granulocytes in the circulation. Boiling the exudate does not seem to alter materially any change in the outpouring of immature granulocytes into the blood stream.

FIG. 2.—THE EFFECT OF AN EXUDATE AT A RELATIVE NEUTRAL pH ON THE NUMBER OF CIRCULATING LEUKOCYTES —●— The effect of an exudate at pH 6.98 ○---○---○ The effect of boiling the same exudate. Note that boiling an essentially neutral exudate does not completely abolish the effect on the absolute white blood count.

exudates. Extending the period of boiling the exudate thirty minutes makes no appreciable difference in the end results obtained. Croton oil in olive oil as an irritant yields similar effects as are obtained with turpentine (table 4). The effect of whole exudate at various pH is represented in the case of single experiments in figures 1, 2, and 3. It is seen that as far as the absolute white count is concerned, boiling an alkaline exudate tends to inactivate it (fig. 1). On the contrary, boiling

FIG. 3.—Boiling an acid exudate, although reducing the ultimate effect probably by abolishing whatever thermolabile LPF may be present in such an exudative material, still leaves a potent effect on the number of circulating leukocytes. —●— The effect on the circulating leukocytes of an exudate at pH 6.8. ○—○ The effect of a similar sample of exudate but brought to a boil before administration.

an acid exudate, although perhaps it diminishes its potency, still does not interfere with its effectiveness (cf. figs. 1 and 3). At relatively neutral pH, boiling the exudate yields somewhat of an intermediate picture (fig. 2).

As pointed out previously, pyrexin or the pyrogenic factor of exudate, the existence of which has been confirmed by Bennett,<sup>9</sup> tends to be present in acid exudates.<sup>10</sup> Smith and Smith have failed to obtain it by utilizing the scheme of extraction outlined by this author, but they have nevertheless shown its presence in the

euglobulin fraction of exudates <sup>11</sup> Tanturi and his collaborators have also shown that there is a pyrogenic factor present in the whole euglobulin fraction of exudates, or as it was formerly called necrosin <sup>13</sup> The term necrosin referred to a combination of necrosin, pyrexin, and the leukopenic factor of exudates Since that time these various components have been dissociated from the euglobulin fraction, particularly of acid exudates <sup>6 14 15</sup> At times the dissociation of pyrexin from necrosin is a difficult procedure It is assumed that this is the difficulty encountered by Smith and Smith <sup>11</sup> In recently published data, the author has shown that when such separation is difficult to perform, allowing necrosin to stand on ice for several weeks will permit pyrexin to settle at the bottom of the container as a precipitate which can easily be recovered as the pyrogenic factor, or pyrexin <sup>15a</sup>

\* Pyrexin injected into right chest instead of introducing it in the circulating blood

† Peripheral blood sample

‡ Cardiac blood sample.

It has been pointed out previously that pyrexin, usually obtained from acid exudates, <sup>10</sup> most frequently in the later stages after its administration tends to yield a leukocytosis in the blood stream <sup>6</sup> Such observations are gathered in table 5 The factor which induces a state of leukocytosis and which is associated with pyrexin probably is closely related, if not identical, to the leukocytosis-promoting factor of acid exudates (tables 3 and 4), for boiling pyrexin fails to inactivate this leukocytosis component These data are assembled in table 6 Vigorous boiling fails to inactivate the leukocytosis-promoting component associated with pyrexin This indicates that this heat stable component seems to differ from the thermolabile LPF <sup>1</sup> When pyrexin or boiled pyrexin is administered, the state of leukocytosis may take place in a few hours or it may occur on the next day The boiled exudate, or for that matter boiled pyrexin, induces a discharge of immature or 1-lobe forms of granulocytes into the circulation as early as one hour, if not before, after the administration of the material These studies appear in table 7 The rapidity of effect

would support the view that the effectiveness of the heat stable component does not seem referable to a secondary tissue injury caused by either boiled exudate or boiled pyrexin

Furthermore, it is of interest that even though boiling tends to inactivate an alkaline exudate when the absolute white cells are studied, yet the percentage of immature granulocytes or single lobed forms still show a rise (fig 1). This would suggest that a study of the differential leukocytic formula is a more delicate test

FIG 4—THE EFFECT OF PYREXIN AND OF BOILING THIS MATERIAL ON THE NUMBER OF CIRCULATING LEUKOCYTES —●— △—△—△ The effect of pyrexin on the number of circulating leukocytes ○—○—○ The effect of boiled pyrexin on the number of circulating leukocytes Note that either pyrexin or boiled pyrexin eventually gives rise to a leukocytosis The initial leukopenia has been shown in an earlier study to be referable to the presence of a leukopenic factor associated with pyrexin \* Samples of blood from the heart or from a peripheral vessel in the lobe of the ear produced essentially similar effects, indicating that the results are not referable to a redistribution of leukocytes in the circulation

than the absolute white count in determining the effectiveness of heated or unheated exudate That this is true has been pointed out previously in the case of rabbit LPF<sup>16</sup>

The effect of pyrexin and of boiled pyrexin is shown in the case of an experiment

in figure 7. It is seen that boiling the material, as in many cases of acid exudates, essentially fails to alter the ultimate effect of pyrexin in inducing a state of leukocytosis in the circulation (cf figs 3 and 4). Peripheral and cardiac samples of blood yield similar results, indicating that the effect is not referable to a redistribution of leukocytes in the vascular system (fig 4).

In order to avoid any criticism of drawing conclusions based only on one animal species, the foregoing series of experiments were repeated on guinea pigs. These

Per cent increase with boiled blood serum 35.6%

\* When boiled there was hardly any coagulated exudate left. The material to be administered was therefore taken and suspended in about a two or three fold volume of distilled water.

latter animals were injected in the right pleural cavity with about 0.2 cc of 5 per cent croton oil in olive oil, and on the following day either the animal was found dead or else thoracentesis yielded a small amount of exudate ranging from 0.1 cc. to 0.5 cc. Postmortem examination revealed the presence of some exudative fluid in the right chest cavity, and this fluid was injected into normal pigs. They received 0.1 to 0.5 cc of either the untreated or the boiled material by injecting it subcutaneously in the groin. White blood cell counts were done by nicking the toe pads at approximately hourly intervals. It is clear from table 8 that exudative material, particularly at an alkaline pH, yields a pronounced rise in the number of

circulating leukocytes of an otherwise normal guinea pig upon administration of the material by the subcutaneous route. Boiling the exudate sample reduced somewhat the effect, but a pronounced influence still remained. In all the observations the exudate induced an average rise in the number of total circulating leukocytes amounting to 152.9 per cent. Boiling such exudative material reduced this figure to 82.4 per cent. This is still an increase, for in an earlier study it has been shown that

\* Percentage of immature granulocytes taken 1 to a few hours after the height of the leukocyte level has been attained.

† Since a very slight amount of the material was obtained following its boiling the material was suspended in distilled water to a volume ranging to about two or three times the amount of boiled serum.

the average maximal variation in guinea pigs is 36.9 per cent.<sup>17</sup> As a further control, the effect of guinea pig blood serum was injected subcutaneously in the groin of otherwise normal animals, this was done in only two animals (table 8). The average increase in the number of circulating leukocytes was found to be definitely less than in the case of exudates. It amounted to 53.8 per cent (cf. with 152.9 per cent in the case of exudates, table 8). Furthermore, when the serum was brought to

a boil, the average rise amounted to 35.6 per cent, a figure not above that encountered in a study of the normal variation in guinea pigs.<sup>17</sup>

Finally, a study was undertaken in guinea pigs to determine the effect of exudates on the differential leukocytic formula. It is clear, as shown in table 9, that a guinea pig exudate induces an early discharge of immature leukocytes into the circulation. This rise is to some extent duplicated in the case of boiled exudates (table 9). On the other hand, both unheated and boiled blood serum fail to show any appreciable changes. In brief, it would appear from the results on the guinea pigs as if in these animals there is also present in their exudative material a relatively thermostable leukocytosis-promoting factor which is essentially absent in guinea pig serum. These results resemble the observations made above on canine exudates.

### DISCUSSION

The foregoing experiments indicate the presence of an additional component concerned with the mechanism of leukocytosis with inflammation. In contrast to the factor previously reported which was thermolabile,<sup>1</sup> the present factor is thermostable. The thermolabile component is found to be associated with the alpha globulins of exudates.<sup>2</sup> The active principle seems to be a polypeptide, perhaps attached to the globulin molecule.<sup>4</sup> When separated from the globulins by aging the material, it is found that the original thermolabile LPF component, now freed of its protein attachment, is also thermostable.<sup>4</sup> The thermostable component described in this paper is usually recovered in greater abundance from acid exudates, in contrast to the labile component, and furthermore this component is found in close association with the pyrogenic factor of exudates or pyrexin. Are the thermolabile component and the thermostable component of the LPF separate substances? This may be the case. On the other hand, it is conceivable that one is dealing with one and the same substance. The leukocytosis-promoting factor, as a polypeptide, seems to attach itself in an alkaline or in a neutral exudative medium to alpha globulins.<sup>2</sup> Consequently, boiling this material denatures the protein and the thermolabile LPF attached to a denatured protein is inactivated. It is also quite possible that in an acid exudate with an appreciable amount of pyrexin present,<sup>10</sup> the LPF slides over and becomes correspondingly attached to the pyrexin molecule. Since pyrexin is also thermostable,<sup>14</sup> and since the LPF polypeptide is likewise thermostable,<sup>4</sup> boiling the combined factors fails to inactivate it. Future studies, it is hoped, will settle this point.

Furthermore, with an acute inflammation, the resultant level of the number of circulating leukocytes cannot be predicted with any degree of certainty (table 1). When the exudate is acid in character, the level in the blood stream tends to be markedly raised (table 2). It would seem as if the rise in the number of leukocytes in the blood is referable to at least two factors, the thermolabile and the thermostable components of the leukocytosis-promoting factor. This tendency is counterbalanced by two other leukopenic factors, the thermolabile leukopenin of exudates<sup>18</sup> and the thermostable leukopenic factor of primarily acid exudates.<sup>4</sup> The combination of these various opposing factors influences the final leukocytic level in the circulation. When the leukocytosis-promoting factors dominate the

resultant effect is a rise in the white blood level. On the other hand, a predominance in the concentration of either, or of both, leukopenic factors results in no appreciable change in the level, or else in a frank leukopenia.

### CONCLUSIONS

There is present in inflammatory exudates, particularly in exudates having an acid hydrogen ion concentration, a thermostable leukocytosis-promoting component, which in conjunction with the previously described thermolabile leukocytosis-promoting factor aids in our understanding of the mechanism of leukocytosis with many inflammatory states. The thermostable component of the leukocytosis promoting factor is recovered in association with the pyrogenic factor or pyrexin. Whether it is essentially different chemically from the active principle present in the thermolabile factor is discussed and remains to be seen.

The resultant leukocyte level in the blood stream with a concomitant inflammation is the resultant of a multiplicity of factors. The rise in the number of circulating leukocytes with inflammation is induced by a combination of the thermolabile and the thermostable components of the leukocytosis-promoting factor of exudates, whereas the decrease in white blood count seems referable to both leukopenin and the leukopenic factor of inflammatory exudates. A predominance in the concentration of any one of these factors liberated by injured cells at the site of an acute inflammation will determine the final level of white cells in the circulation.

## EXPERIMENTAL THORACIC DUCT FISTULA

### OBSERVATIONS ON LYMPHOCYTE OUTPUT

B<sub>y</sub> WILLIAM W L GLENN, M D , FRANCIS X BAUER, M D , AND  
SAMUEL L CRESSON, M D

SINCE the adaptation of polyvinyl chloride and polyethylene to the making of cannulae, several investigators<sup>1</sup> \* have been able to produce thoracic duct fistulae in the dog which are free-flowing for as long as 8 days. Thus is provided, for the first time, a means for continuing observations on the lymphocyte output from the thoracic duct. The findings may have implications as to the production, circulation and fate of the lymphocyte.

It has been known for many years that large numbers of white cells, 98 per cent of them lymphocytes, are constantly passing into the blood stream from the thoracic duct. Yoffey<sup>2</sup> has found that a 10 kilogram dog discharges, on the average, about 200 million lymphocytes hourly into the blood stream through the thoracic duct. From this rate of lymphocyte output he estimated that in the dog there is a complete replacement of the blood lymphocytes twice daily. Sanders, Florey and Barnes<sup>4</sup> and Adams, Saunders and Lawrence<sup>5</sup> have recently determined that there is a similar rate of replacement of the blood lymphocytes in the cat. The former also estimated that in the rabbit the blood lymphocytes are replaced at least 5 times a day. It is important to note, however, that in all of these previous experiments, the thoracic duct fistulae have been created under a general anesthetic and have drained for a few hours only.

Investigators are not in agreement over the fate of the lymphocyte after it enters the blood stream. Yoffey and Drinker,<sup>6</sup> for example, on the basis of the number of lymphocytes in lymph prior to passage through a lymph node, maintained that only one lymphocyte in 32 that enters the blood from the thoracic duct eventually re-enters a peripheral lymphatic. They believed that to this small extent a recirculation of lymphocytes takes place. Sanders, Florey and Barnes<sup>4</sup> did not believe that any lymphocytes are recirculated through the lymphatics and assumed that all of the lymphocytes passing through the thoracic duct are newly formed cells. Ehrlich,<sup>7</sup> on the other hand, thought that many lymphocytes leaving the blood are recirculated through the lymphatics. Considering the several theories regarding the fate of lymphocytes, Ehrlich stated: "After having been formed in the lymphatic tissue, the lymphocyte passes through the lymphatics, and possibly, also through the veins of this tissue, into the blood stream, where it circulates for several hours. After this period some leave the blood through the mucous membrane of the gastrointestinal tract, others, probably the majority, return to the lymphatic tissue, and in the lymph nodes, also through the peripheral lymph vessels. It is likely that many of these lymphocytes go on and return to the blood stream, and in fact this cycle may be repeated several times."

From the Surgical Research Department, Jefferson Medical College, Philadelphia, Penna.

Adams, Sanders and Lawrence<sup>3</sup> believed that although the recirculation of lymphocytes can be demonstrated it is not of great significance when one considers the total lymphocyte replacement occurring via the thoracic duct. In discussing the effect of thoracic duct cannulation on the concentration of blood lymphocytes, these same investigators concluded that the real test of the effect of cannulation of the thoracic duct would be to continue the cannulation for much longer periods of time. This was not possible before the use of plastic cannulae owing to the rapid clotting of lymph in the glass cannulae used by previous investigators.

### METHOD

Using dogs under local anesthesia the thoracic duct was cannulated in the neck with a cannula made from polyethylene tubing. The right lymphatic duct was ligated and divided a week or more prior to the thoracic duct cannulation. The technic is described in detail in another paper. Studies on the output of lymphocytes through the thoracic duct fistulae were carried out on 7 dogs. One experiment where lymphocyte counts were made has been omitted due to frequent clotting of the lymph in the cannulae. Many red blood cells were present in the thoracic duct lymph of this animal. Total white cell counts and differential smears were made at about the same time each day on peripheral venous blood. At least 400 cells were counted in the differential blood smears. Because of the difficulty of distinguishing large lymphocytes from mononuclear cells in the peripheral blood smears, small lymphocytes only are recorded. Total white cell counts on the lymph were usually made several times daily when the fistulae were flowing. The number of counts varying between a single count on one day in one experiment to 54 counts on one day in another experiment. Calculation of the lymph flow was made simultaneously with many but not all of the lymphocyte counts. Where simultaneous lymph flow was not determined the counts were excluded from the results. As pointed out by Rous<sup>4</sup> and Drinker and Yoffey,<sup>5</sup> the ideal method for determining the lymphocyte output through the thoracic duct would be to collect the lymph over a period of time, adding an anticoagulant, and then to count the cells in the measured volumes. In these experiments the volume of lymph drained, usually over a ten to thirty minute period, was measured and the lymphocyte output for that period was calculated from a count taken during the period directly from the cannula. At least one differential smear on the lymph was made each day at the same time as the differential blood smear.

### RESULTS

The results of these experiments are recorded in table 1. It is evident that there was usually a fall in the blood concentration of small lymphocytes. This fall was frequently marked but at no time did it reach zero. The blood concentration of small lymphocytes reached the lowest point generally on the second or third day of drainage and thereafter either remained the same or increased gradually. Where counts on the blood were continued after the fistula had closed it was noted that the return of the lymphocyte concentration in the blood to preoperative levels took place slowly. In experiment 8 a splenectomy was performed several weeks before the fistula was made. There was no greater decrease in the number of small lymphocytes in the blood in this dog than in the other dogs where the spleen was left intact.

A study of the lymphocyte concentration of thoracic duct lymph shows that where there was adequate lymph drainage beyond the second or third day there was usually a drop in the calculated number of lymphocytes passing out through the thoracic duct per unit of time. Experiment 1 is of particular interest. On cannulation of the thoracic duct in this dog a profuse flow of lymph and a relatively low lymphocyte count was found. It was decided to make a deliberate attempt to obtain a maximum flow of lymph during the period of fistula drainage. Fluids were administered chiefly by mouth. During the last twenty-four hours of fistula drainage more than 6000 cubic centimeters of fluid were given. The maximum measured flow of lymph during a one hour period on this day was 368 cubic centimeters. Despite this very profuse flow of lymph there was only a moderate drop in the calculated number of lymphocytes passing through the thoracic duct per unit of time (table 1).

In several experiments sufficient data was available so that observation could be made on the relationship between the rate of flow through the thoracic duct and the lymph count per unit of time.

of lymph early and late in the period of fistula drainage. It appeared that for the first two to three days after the fistulae were established an increase in the flow of lymph as followed the administration of fluid was accompanied by an increase in the number of lymphocytes per cubic millimeter of lymph. After several days of free drainage, however, an increase in lymph flow usually resulted in a fall in the number of lymphocytes per cubic millimeter of lymph. It was observed that if the lymph flow were allowed to fall to a very low level after a period of profuse flow a concentration of the lymphocytes took place for a time but as the flow continued to drop the number of lymphocytes decreased also. An increase in the lymph flow under these conditions was accompanied by a prompt rise in the lymphocytes in the lymph. In table 2 excerpts from the protocol on experiment 8 illustrate these changes.

Smears for differential counts made on specimens of thoracic duct lymph did not reveal any apparent changes at first but after several days of drainage there was observed a fall in the percentage of small lymphocytes (table 3). Although the total white cell count in the lymph at the time of the differential smear was sometimes higher on the final day of fistula drainage than on the first day it can be seen from table 1 that an average of several counts always revealed a lower total white cell count on the final day of drainage. The counts recorded in table 3 were made in the early morning when the lymph flow had diminished with consequent concentration of the cellular elements.

### DISCUSSION

The creation of a thoracic duct fistula under local anesthesia in the dog which will drain continuously for a number of days is not difficult but the animal so prepared requires almost constant attention during the period of fistula drainage. In several of the experiments reported the animals were observed continuously over consecutive 24 hour periods. In the majority of experiments, however, observations were made over a 16 to 18 hour period daily as long as the fistulae remained open.

The problems encountered when using plastic cannulae are relatively minor and in marked contrast to the difficulties encountered when using cannulae made of glass or other nonclot preventing materials. Nevertheless, plastic cannulae become blocked occasionally. Factors that predispose to blockage must be carefully

avoided especially the dehydration of the animal and contamination of the mouth of the cannula with tissue fluid from the wound through which the cannula protrudes. Small clots in the cannula should be watched for and promptly removed. This can best be accomplished by twisting a fine wire in the substance of the clot near the mouth of the cannula. If the lymph contains large numbers of red cells, which it occasionally does, early blockage of the cannulae can be anticipated. The loss of electrolytes, fat and protein through a continuously draining thoracic duct fistula is of major importance. An animal so depleted would soon die unless some effort were made to replace these losses. An attempt was made to replace the sodium and chloride loss but no protein or fat was administered except for a small measured amount of the latter given for the purpose of a fat absorption study. A detailed account of the protein loss in these animals is given in another paper. The protein concentration in the lymph and blood declined steadily during the period of fistula drainage, a fall of 2 to 2.5 grams per cent total protein over a period of four to six days of fistula drainage was the rule. Where done, the albumen-globulin rates remained the same after depletion but only a few such determinations were made.

The drop in the concentration of blood lymphocytes after thoracic duct fistulae were produced is in accord with the findings of others who have worked with thoracic duct fistulae of short duration. Sanders, Florey and Barnes<sup>4</sup> and Adams, Sanders and Lawrence<sup>5</sup> showed that a similar fall in the concentration of lymphocytes in the blood occurred following operations where no lymph fistulae were produced. The evidence of Adams, Sanders and Lawrence is particularly convincing on this point. The cats used in their experiments were anesthetized with dial and urethane intraperitoneally. The effects on the blood lymphocyte levels of the anesthetic agents and their mode of administration should probably also be checked since the drop in the blood lymphocytes in our experiments followed cannulation of the thoracic duct under local anesthesia.

The finding of a decreased lymphocyte output after several days of continuous lymph drainage is of considerable interest. If there is an appreciable recirculation of lymphocytes the failure of many millions of these cells to reach the blood would after a time cause a fall in lymphocyte output through the thoracic duct. On the other hand, a decreased lymphocyte production, in response perhaps to the prevailing experimental conditions, would likewise cause a drop in lymphocyte output. We have presented no conclusive evidence one way or the other. It has been demonstrated by Rous<sup>8</sup> and by Drinker<sup>10</sup> that there are many lymphocytes in the lymph nodes which, under conditions of normal lymph flow, do not enter the efferent lymphatics. With an increased flow of lymph through the nodes, however, there is a sharp increase in the number of lymphocytes in the efferent lymphatics. Although this indicates that there is a surplus of lymphocytes in the nodes it gives no indication whether these cells were formed in the nodes or whether they arrived there after having first circulated through the blood.

In experiments of several days' duration there are many factors which may influence lymphocyte production. Starvation, known to have a depressant effect on lymphoid tissue, may have been a factor in these experiments. According to Jackson,<sup>11</sup> inanition results in a characteristic atrophy of lymphoid tissue with prompt

recovery accompanying refeeding. He states that lymphoid tissue is particularly sensitive to fat deficient diets. In our experiments no protein and a negligible amount of fat was given during the period of fistula drainage, although all dogs received glucose or sucrose from which fat may have been formed.<sup>12</sup> The amount of sugar given varied from the equivalent of 15 calories per kilograms per day in experiment 8, to 50 plus calories per kilogram per day in experiment 2. Some of the carbohydrate given was undoubtedly lost through the fistulae. During the period of fistula drainage there was a rapid and usually appreciable fall in the protein concentration of both serum and lymph in all of these experiments.\* Jolly<sup>13</sup> observed an appreciable loss of weight in the cervical and popliteal lymph nodes, as well as in other lymphoid structures, of two dogs starved for six and seven days. In two of our experiments, 2 and 4, one popliteal node was removed under local anesthesia at the time that the thoracic duct fistulae were produced and the opposite popliteal node was removed, under local anesthesia, just after the fistula closed. There was a loss of weight in the nodes removed after fistula drainage that averaged 213.5 milligrams for the 2 animals. This was compared with the average difference in weight of 42.5 milligrams, with a maximum difference of 90.5 milligrams between the two popliteal nodes in 8 control animals sacrificed for other reasons. Microscopic sections of the glands in the 2 fistula dogs did not show any characteristic changes in the nodes removed after fistula drainage. It was not possible to correlate the decrease in lymphocyte output through the thoracic duct with the histologic findings in the popliteal nodes.\*

An increase in the blood leukocyte level accompanying the production of thoracic duct fistulae has been observed by Adams et al.<sup>6</sup> and others. With regard to the lymphopenia that usually accompanies a blood leukocytosis,<sup>6</sup> it is interesting to note (table 1) that the rise in leukocytes preceded any significant fall in the lymphocyte output through the thoracic duct fistula.

The significance of the changes in the percentage of the various sized lymphocytes in thoracic lymph (table 3), after several days of fistula drainage, is not clear. Wiseman<sup>14</sup> states that size is not strictly a function of age in lymphocytes. He regards the degree of basophilic staining of the cytoplasm as the more evident and reliable indication of the youth of the cells. In our experiments there appeared to be after several days of fistula drainage an increase in the percentage of cells showing a deeply basophilic cytoplasm. From the observations made by Wiseman, these findings might be interpreted as indicating that the drop in lymphocyte output through the fistula was at the expense of the older, less basophilic, cells.

#### SUMMARY

Thoracic duct fistulae in dogs created under local anesthesia and draining continuously from two to eight days have been utilized for the study of lymphocyte output. Too few observations have been made for them to be statistically significant.

\* The authors would like to express their appreciation to Dr. Joseph Feldman and Dr. Henry Bunting of the Department of Pathology, Yale University School of Medicine, for the histologic examination of the lymph node sections.

cant. It is realized that after several days of fistula drainage, factors other than the simple loss of lymphocytes through the thoracic duct fistula may have influenced the lymphocyte output. The necessity for taking into consideration the many factors which may influence lymphocyte output in the evaluation of the effect of any single factor is emphasized.

#### ACKNOWLEDGMENT

The authors would like to express their appreciation to Dr. John H. Gibbon, Jr. and to Dr. Cecil K. Drinker for their helpful suggestions in the accomplishment of this work.

# THE EFFECTS OF ROENTGEN RAYS ON THE INFLAMMATORY CELLS OF THE MOUSE AND RABBIT

By WILLIAM A. TOWNSEND, M D, AND BERRY CAMPBELL, PH D

ROENTGEN RAYS have been used regularly by radiologists<sup>1-12</sup> for the treatment of a large variety of inflammatory conditions, but experimental morphologic studies, as shown below, have revealed no reliable evidence to explain why roentgen rays should be of value. We undertook this problem to determine whether morphologic alterations of the inflammatory cycle could be induced by a variety of roentgen ray doses applied at times before and after inciting an inflammatory reaction in mice and rabbits. Our quantities and times of irradiation include and extend beyond those used by most earlier workers.

Sturges and Levin<sup>14</sup> were the first to study the effects of roentgen rays on leukocytes they defined as inflammatory. They found that either intravenous yeast emulsion injections or roentgen rays, when applied separately, caused a depression of the lymphocytes in the circulating blood of frogs, whereas roentgen rays superimposed on the effect of yeast emulsion had no additional action. They concluded that if the leukocytes remaining after administration of yeast emulsion were inflammatory cells, then inflammatory cells were radioresistant.

The radioresistance of inflammatory cells was further supported by Maximow<sup>15</sup> who heavily irradiated inflammatory sites locally in the subcutaneous tissue of rabbits. The earliest examination was made eleven days following irradiation when the inflammatory site contained only leukocytes and polyblasts in a gelatinous fibrin substance. The fibrocytes had been destroyed as well as collagenous fibers, so it was concluded that either leukocytes and macrophages were extremely radioresistant or that the initial infiltration had been destroyed and replaced by a second inflammatory infiltration.

Soto, Brunschwig, and Shultz<sup>16</sup> produced subcutaneous abscesses in rabbits with a variety of bacteria and with croton oil. The animals were given whole body irradiation at intervals of 24 hours before injection and immediately, 5 hours, 24 hours, and 7 days following injection of the irritant. The dose applied was 600 r (200 KV, 25 ma, 50 cm focal distance, 1 mm Cu plus 1 mm Al filter). The abscesses were mainly observed grossly but some were observed histologically. In neither case was any specific evidence found which indicated roentgen rays were of value clinically or the cause of histologic changes.

Hayer<sup>17</sup> locally irradiated (600 r) an area on a dog's thigh immediately following the subcutaneous injection of turpentine and observed that the abscess developed as in the normal animal. A similar observation was made following local irradiation of the spleen, but whole body irradiation markedly inhibited abscess development until a later period. The reason for these results was thought to be the leukopenia following whole body irradiation.

A number of authors have observed that roentgen rays decreased the number of

From the Department of Anatomy, University of Minnesota, Minneapolis, Minn.

inflammatory cells. Mitternau<sup>11</sup> irradiated acute aseptic inflammation induced by catgut sutures in the skin and subcutaneous tissue of guinea pigs and reported a decreased number of inflammatory cells within six and twenty four hours following irradiation. This decrease was also found by Fukase<sup>12</sup> within twenty four hours following irradiation of aseptic uterine incisions in the abdominal skin of rabbits. Fukase's result was confirmed by Tannenberg and Bayer<sup>13</sup> who employed a similar technic. Mischtschenko<sup>14</sup> and his co-workers examined inflammatory exudate smears two, three, and four days following irradiation of staphylococcic inflammatory sites in rabbits. They concluded that an increased leukocytic destruction as well as an increased phagocytosis was caused by irradiation.

An increased leukocytic infiltration was found by Buhtz<sup>15</sup> within a few hours following irradiation of rabbits prepared as Fukase had done previously. Buhtz had his conclusion confirmed by Tannenberg and Bayer.<sup>16</sup> Poumeau Delille<sup>17</sup> found an increased neutrophilic infiltration into rabbits' subcutaneous tissues within two days following irradiation of multiple aseptic abscesses with smaller doses of roentgen rays than used by the preceding authors. Doses over 150 r were said by the latter author to result in decreased infiltration. Burnet de Rochebrune<sup>18</sup> reported that roentgen rays imposed upon formic acid on a rabbit's skin resulted in an exudation whereas neither roentgen rays nor formic acid had this effect when applied separately.

As a standard preparation we have used subcutaneous experimental inflammation in the mouse produced by an injected inflammatory agent. A clear description of the time sequences and cytogenic development of the acutely inflamed areolar tissue of the rabbit has been contributed by Kolouch.<sup>19</sup> For a review of the earlier literature on the inflammatory article, reference is made to the elaborate discussion in the aforementioned paper, and to the textbook of Maximow and Bloom.<sup>20</sup> Kolouch studied the inflammatory cycle of rabbits and introduced the Romanowsky-stained loose connective tissue spread which was employed by the authors of this paper. This technic, which will be described below, allowed the direct comparison of cells in the connective tissue with those of the blood smears and splenic imprints.

The nomenclature of the various inflammatory cells has varied in the past with different authors. We shall attempt to follow Maximow's nomenclature as closely as possible, but convenience suggests certain modifications. The terms ameboid and resting wandering cell have been used for the resident tissue cells which are known variously as clasmatoocytes, histiocytes, tissue macrophages, etc. To indicate the cytomorphic line from the lymphocyte to macrophage we have introduced at the suggestion of Bloom, the new term intermediate polyblast.

#### MATERIALS AND METHODS

An aseptic irritant composed of egg albumin into which a small amount of india ink as a marker had been mixed was used to incite the inflammatory cycle in the mice and rabbits. This irritant was injected in .07 to .09 cc. quantities into the loose subcutaneous connective tissue on the lateral part of the abdomen. A single injection was made into each of the mice which were then killed at appropriate intervals with ether. About 200 mice were used in experiments to standardize the inflammatory cycle preparation (see below). The rabbits were similarly treated except that severe inflammatory sites were made on each animal.

According to the technique introduced by Kolouch the loose subcutaneous connective tissue of the inflammatory site was removed placed on a clean glass slide and spread, rapidly air dried and stained with Wright Giemsa

The mice were given whole body irradiation in groups of three or more in a small cardboard box. The animals were irradiated with a 7 ma superficial therapy machine set at 100KV emitting 100 skin roentgens in 1 3 minutes with no filter and a 30 cm focal distance. The doses varied from 25 r to 1600 r to the whole body which was applied at various times preceding and following the injection of the irritant. A total of 150 mice were irradiated in these experiments

The rabbits to be locally irradiated were injected with a similar irritant in two sites one on either side of the abdomen. The tissues were removed and prepared by the method of Kolouch after the rabbits had been killed at appropriate times by injected air. Twenty four hours following injection of the irritant the rabbits were irradiated on one side only under intravenous Nembutal anesthesia. Localization was accomplished by means of a cone three centimeters in diameter having a 15 5 cm focal distance. The roentgen rays were produced by a 7 ma superficial therapy machine set at 100 kV which emitted 170 air roentgens per minute with 1 2 mm of aluminum filter

Five rabbits were given whole body irradiation with the same machine similarly filtered but emitting roentgen rays at the rate of 64 8 r per minute with the focal distance raised to 33 cm. Four sites were injected on each rabbit's abdomen for the purpose of studying morphologic variations between the various inflammatory sites

Eight rabbits were given whole body irradiation with a 15 ma deep therapy machine set at 220 kV which emitted 106 r per minute with 2 mm of copper plus 2 mm of tin filter at a 33 cm focal distance. The half value layer was 1 35 mm of copper. Four sites were also injected in each animal of this series

### THE INFLAMMATORY CYCLE OF THE MOUSE

As previous literature has not described the normal cycle of inflammation in the mouse as revealed by this method, we present the following observations as a necessary basis for the irradiation experiments. The fibrocytes (fig 1) of this species differ from those described by Maximow in the human connective tissue in having a larger number of distinct chromatin clumps in an otherwise fine reticular chromatin pattern. The fibrocyte nuclei are the largest and palest staining in the connective tissue and are round or oval in outline. The indistinctly delimited cytoplasm is slightly basophilic and more homogeneous than that of the wandering cells. The fibrocyte cytoplasm occasionally contains india ink but no other particles

The wandering cells (fig 1) differ from the fibrocytes in having smaller, more deeply staining nuclei with a heavier, denser chromatin network, the cytoplasm being more basophilic, granular, and vacuolated. The cytoplasm has a distinct boundary in the ameboid wandering cells and is indistinct in the fixed wandering cells. Some of the wandering cells begin phagocytosis in the inflammatory site within one hour. These resident phagocytes give rise to large histogenous macrophages by gradual transitional forms which show increasing cytoplasmic and nuclear volume. As the nuclear volume increases, the chromatin blends into the parachromatin until frequently the nucleus appears homogeneous. This cell is relatively more frequent in the earlier hours and is considerably less frequent after the first day of the inflammatory cycle. Kolouch called this cell the activated clasmocyte

The lymphocytes of the mouse are morphologically similar to those in the human. The nuclei are either round or indented, with chromatin clumps which blend into the parachromatin. The scanty cytoplasm is deeply basophilic and occasionally

contains small vacuoles and a few fibrils. Lymphocytes and intermediate polyblasts are very occasionally found in the normal connective tissue.

The lymphocytes first migrate to the inflammatory site about the capillaries within four hours after the application of the irritant and large numbers are present within twelve hours.

A continuous variable infiltration, as contrary to the heavy initial immigration, was seen throughout the 108 hour period of observation. Within two hours after the initial infiltration began some lymphocytes were acquiring an increased nuclear and cytoplasmic volume which characterized early intermediate polyblast development (fig. 4). In the inflammatory site the evolution of the nuclei of the lymphocyte to that of the intermediate polyblast and finally to the macrophage could be followed in detail. The clumped chromatin of the lymphocyte forms strands and gradually differentiates into a heavy reticular pattern containing several distinct chromatin blocks (figs. 5b, c). Associated with the formation of the polyblast chromatin pattern was a tendency for many intermediate polyblasts to acquire a kidney shaped nucleus (figs. 4 and 5). As the chromatin became more like that of the reticulum cell, the nucleus filled out to the round nucleus of the macrophage (fig. 5c). Both cytoplasm and nucleus increased in volume during this process with the former becoming less basophilic and more granular and spongiiform. This development of the macrophage was completed in some cells within twenty-four hours and was assumed to be from those lymphocytes first infiltrating. Due to the continual infiltration of lymphocytes (fig. 6) a complete transitional series could be seen up to 108 hours. The intermediate polyblasts even in the early stages of development were seen to be capable of phagocytosis.

Although the great majority of lymphocytes formed intermediate polyblasts, an occasional lymphocyte underwent nuclear and cellular pyknosis and fragmentation. The degeneration was identical with the degeneration of lymphocytes in the spleen as discussed elsewhere. Rarely a pyknotic or fragmented nucleus could be found in cells resembling the intermediate polyblasts or macrophages. More rarely these degenerate cells contained phagocytosed material.

The fibrocytes were seen in mitosis in both the control and inflamed tissues, and especially in the later stages of inflammation. Rarely macrophages or intermediate polyblasts were found in mitosis.

The neutrophils of the mouse differed from those found in the human in having one or several lobes which formed a closed ring. A study of neutrophil development in the mouse clearly indicated that the single lobed, thick ringed nuclei were younger than the multilobed nuclei. The single lobed cell was especially prominent in the primary infiltration of neutrophils which had begun within one hour following the injection of the irritant. Large numbers of neutrophils underwent cellular fragmentation (fig. 2) and were ingested by histogenous macrophages within a few hours following infiltration. As in the case of the lymphocytes, secondary infiltration occurred throughout the period of observation. The neutrophils were found in the normal tissue in about the same frequency as the lymphocytes.

The connective tissue of the mouse also contains mast (fig. 1c) cells which are filled with metachromatic granules which obscure the nucleus. The entire cell is

FIG. 6—Connective tissue spread from the mouse inflamed tissue showing a secondary infiltration of lymphocytes and neutrophils 84 hours following injection of the irritant. The small dark granules are from a ruptured mast cell Wright-Giemsa  $\times 600$

somewhat larger than the nucleus at 48 hours. These cells underwent no specific morphologic change during the inflammatory cycle although several were ruptured in the inflammatory site with consequent scattering of the granules.

#### EFFECTS OF IRRADIATION ON INFLAMMATORY CYCLE OF MOUSE

*1. Effect of irradiation on the inflammatory site of the mouse.* As the control series showed that the time of maximal lymphocytic infiltration in the inflamed areolar tissue occurred at twelve hours, this preparation was studied most thoroughly. The inflammatory cell population at this stage, in addition to the large number of lymphocytes, consists of invasive neutrophils, of lymphocytes which have differentiated into intermediate polyblasts and of histogenous macrophages. Thus the effects upon each of these cell varieties may be determined.

Irradiation of the twelve hour inflammatory site produced vacuolation in the intermediate polyblasts at dosages of 50 r to 500 r. Throughout the cytoplasm of the affected cells appeared large numbers of small clear vacuoles. A similar type of vacuole is very occasionally seen in the normal cell but never in any large numbers. Figure 7 shows the appearance of the intermediate polyblast twenty-four hours after a dose of 400 r. The vacuoles at these dosages were observed to appear at twelve hours, reach their greatest frequency at twenty-four hours, and decrease in the later stages. It would seem then that they represent a reversible alteration and hence they have been differentiated from the frank degenerative changes—fragmentation, karyorrhexis, chromatolysis, and irregularity of nuclear outline—that appear, in addition to vacuolation, at doses of 700 r or more. The preparations receiving 1200 r and 1600 r showed extensive degeneration of the intermediate polyblasts at twenty-four hours (fig. 8). This resulted in a decrease in the number of inflammatory cells relative to the fibroblasts in the tissue spreads.

The macrophages showed a greater resistance to the irradiation than did the intermediate polyblasts. Vacuolation similar to that described above, appeared at 900 r with degeneration showing at 1200 r and more (fig. 9) though differentiation in this stage cannot be made between the hematogenous and the histogenous macrophages. Consequently the relative radiosensitivities of these two cell lines cannot be ascertained. Evidence presented below indicated that up to 1200 r, the wandering cells of the tissue are unaffected.

A decrease in the number of lymphocytes and neutrophils became apparent in those preparations which had received 900 r and larger doses.

Loss of ability of the inflammatory cells to localize the irritant was evident in the preparations exposed to doses higher than 700 r. The India ink used as a marker for the egg white, was spread out over a larger area following these heavy exposures and contrary to the normal picture, tended to be phagocytosed by the fibroblasts. Whether these usually inactive cells were activated by the large doses or were responding to lack of competition of the normal scavenger cells is problematic.

*2. Irradiation of the four hour inflammatory site.* In this series only dosages of 700 r or less were tested. The effects were of the same nature as those described in the previous section though of lesser severity.

*3. Irradiation of the inflammatory site at the time of injection or at or shortly preceding*

*the time of injection* Low dosages in this series produced no alteration of the inflammatory site. At 1200 r doses, no degeneration of macrophages of tissue origin or of intermediate polyblasts was seen (fig. 10). A normal infiltration of both lymphocytes and neutrophils was found up to twenty-four hours with a decrease noticeable

FIG. 7—Connective tissue spread from a mouse inflamed tissue showing vacuolation twenty four hours following irradiation with 400 r (a) vacuolated intermediate polyblast (b) nonvacuolated intermediate polyblast (c) degenerate lymphocyte of type seen in nonirradiated inflammation. in the later stages. As a severe leukopenia was noted in the circulating blood in less than twenty-four hours, normal infiltration at this stage seemed the more remarkable. It was further noticed that the cells derived from the invading lymphocytes did not undergo degeneration as in the other experiments where the inflammatory site was irradiated after they had invaded the tissues. A plausible explanation for the greater resistance, under these circumstances, of the infiltrating lymphocytes and their derivatives, the intermediate polyblasts and hematogenous macrophages,

is that the mononuclear leukocytes had already been destroyed in the blood and only the mononuclear leukocytes remained.

No degeneration of the histiocytes or macrophages was seen with these massive doses, indicating the high resistance of this cell type.

2. *Irradiation of the rabbit*—*Local irradiation* Three mice only were used in this part of the experiment, one for each of the periods. They were killed twenty-four hours after the irritant was injected. All showed a greatly decreased lymphocytic infiltration and scarcity of intermediate polyblasts. The histogenous macrophages were present in normal numbers and consequently outnumbered the hematogenous inflammatory cells, a numerical relationship which is the reverse of that seen in the controls. A slight infiltration of lymphocytes was present.

TABLE 1. Summary of Rabbit Experiments

### EFFECTS OF IRRADIATION ON INFLAMMATORY CYCLE OF THE RABBIT

1. *Local irradiation on the inflammatory cells in rabbits* Twenty-one rabbits were irradiated locally on the twenty-fourth hour following the injection with dosages ranging from 80 r to 1000 r. Examination was made at intervals from 2 to 96 hours following the irradiation and no deviation from the controls were found with regard either to the morphology or the numerical frequency of the inflammatory cells. In addition one rabbit was exposed to 1000 r twenty-four hours before the injection and examined twenty-four hours later. No deviation from the control was noted.

2. *The effects of general body irradiation on the rabbit* Twelve rabbits were given whole body irradiation at 700 r or 1000 r and examined at intervals ranging from 5 hours to 96 hours. Of 5 animals given 1000 r (at 220 KV), 4 showed a markedly reduced infiltration of leukocytes. In the fifth only a moderate decrease in the leukocytic infiltration was seen. In all of the experiments, no abnormalities of the inflammatory, or tissue cells were observed.

### DISCUSSION

Our experiments did not reveal any acceleration of the inflammatory cycle at any dosage, though they were specifically designed for detecting such a phenomenon if

it should exist. No effects of any kind were observed at dosages below 250 r in the mouse or 1000 r in the rabbit. General body irradiation prior to the setting up of the inflammatory cycle decreased the infiltration of neutrophils and lymphocytes in dosages of 700 r or more in mice, and 1000 r in rabbits. Our evidence would indicate that the decreased infiltration is for the most part a reflection of the profound leukopenia induced. Local irradiation in the rabbits produced no such effect.

A striking resistance of all the inflammatory cells was noticed. The lymphocytes in the tissues showed no degenerative changes, indicating a great radioresistance in contrast to those observed in the hematopoietic organs but in agreement with experiments on blood.<sup>8</sup> The intermediate polyblast, which proved to be the most easily affected of the inflammatory cell population, showed no structural abnormalities, under the conditions of the experiment, in response to doses of less than 250 r and exhibited frankly degenerative phenomena at irradiations of 700 r or more. It was apparent that the macrophages of tissue origin (as well as their precursors, the wandering cells) are more radioresistant than at least some of the macrophages developing from lymphocytes. Large doses (1200 r) given at a time preceding the inflammatory stimulus resulted in no degenerative phenomena in these cells following the onset of the inflammatory cycle. Degeneration did occur in macrophages when irradiation at this dosage was performed twenty-four hours following the injection of the inflammatory agent. With 900 r, vacuolation could be observed in macrophages in those sites irradiated after the formation of the lymphocyte derivatives. No degenerative phenomena were observed in the infiltrating lymphocytes at the greatest dosage (1200 r). Neutrophils which had invaded the inflammatory site likewise proved resistant to all doses studied.

In our results, there is nothing to correlate with the conclusions of many clinicians that roentgen therapy is of great value in a number of inflammatory conditions. It is possible that a study similar to this on septic inflammation, or even the inclusion of the late stages would have made our results more confluent with previous literature. We wonder, though, whether the phenomenon of decreased infiltration which we observed in response to massive whole body exposure has been misinterpreted by some who were looking for an acceleration of the inflammatory cycle by x-rays.

Our study of the inflammatory cycle in the mouse substantiates the study by Kolouch in the rabbit. The neutrophils began invasion of the inflammatory site within one hour following injection of the irritant and reached a maximum within four to six hours. They quickly underwent degeneration and were ingested by the macrophages. Lymphocytic infiltration occurred within four hours after the injection of the irritant and immediately or very shortly afterwards began a transformation into intermediate polyblasts. The maximum number of lymphocytes was found in the tissues within twelve hours following injection of the irritant. Kolouch's paper dealt with the sequence of cell types and not quantitatively with the populations. Our findings on the variability of the secondary infiltrations of both granulocytes and lymphocytes indicate that a large number of preparations are necessary in order to deal adequately with the latter question.

## CONCLUSIONS

1. No acceleration of cell differentiation of the inflammatory cycle is induced by treatment with roentgen rays.
2. The decreased infiltration of the inflammatory site caused by massive whole-body exposures before the inflammation was set up or early in the cycle is due to the leukopenia induced in the circulating blood.
3. Of the inflammatory cells of the mouse the intermediate polyblast (a lymphocytic derivative) is relatively the most radiosensitive with structural abnormalities noticeable following 250 r. The macrophages derived from the intermediate polyblasts show alterations following doses of 700 r or more. Wandering cells, histogenous macrophages, infiltrating lymphocytes and neutrophils show no morphologic abnormalities following doses as high as 1,000 r.
4. The ability of the tissue to prevent the spread of the inflammatory agent is decreased following dosages of 700 r or more.
5. The inflammatory cells of the rabbit are markedly more resistant than those of the mouse.

## ACKNOWLEDGMENT

The authors wish to express their indebtedness to Dr. D. Wayne Townsend for aid in irradiating many of the animals.

# A PRELIMINARY STUDY OF THE RELATIONSHIP BETWEEN LACTOBACILLUS LACTIS DORNER RESPONSE AND CLINICAL ANTI-PERNICIOUS ANEMIA ACTIVITY OF LIVER EXTRACTS

By WILFRID F. WHITE, M.S., JOHN R. MOTIL, M.D., AND EDWIN E. HAYS, Ph.D.

SINCE the isolation of vitamin B<sub>12</sub> in crystalline form was announced in this country,<sup>1</sup> several investigators have published the results of clinical studies with the pure material on pernicious anemia patients. These studies, while incomplete, leave little room for doubt that vitamin B<sub>12</sub> is a potent anti-pernicious anemia factor. Allowing for individual variation of patients, the responses have been proportional to the amounts of vitamin B<sub>12</sub> used and in turn proportional to the microbiologic activity as measured by *Lactobacillus lactis* Dorner. Thus, the picture with regard to clinical response to pure vitamin B<sub>12</sub> is rapidly becoming clear. However, in view of the observed wide variation in the *Lactobacillus lactis* Dorner potency exhibited by commercial parenteral liver extracts,<sup>1</sup> we have felt the need for an investigation of the relationship between the microbiologic response obtained with this micro-organism and the clinical response to both oral and parenteral liver extracts.

We have accumulated assay data on 69 pernicious anemia cases in which a variety of liver extract preparations were used. The preparations were prepared by several different methods, but each was carefully assayed microbiologically by means of the *Lactobacillus lactis* Dorner organism. We believe that the data accumulated are sufficiently pertinent to justify publication of these preliminary results.

**Samples\*** The samples can be classified as follows: (1) Experimental oral extracts made from several crude liver fractions including the supernatant of autolyzed whole liver, whole aqueous extracts of liver and 70 per cent alcohol soluble fractions of aqueous liver extract; (2) experimental crude parenteral solutions in the 2-5 U.S.P. units per cc. classification made from the 70 per cent alcohol soluble fraction of aqueous liver extract; (3) experimental refined parenteral solutions in the 15 U.S.P. units per cc. classification and prepared by several different experimental processes. The preparations for oral administration were given in three equal daily doses. The crude parenteral solutions were given twice a week and the more highly refined concentrates were given by a single parenteral injection every fourteen days.

**Clinical Testing** All subjects tested were anemic either as a result of no previous liver therapy or were in relapse due to a lapse in treatment. The latter group of patients had not received liver or arsenic for the period recommended by the Anti-Pernicious Anemia Board of the U.S. Pharmacopoeia.<sup>2</sup> Before liver therapy was started, each patient was hospitalized until the physician in-charge was satisfied that the diagnosis of Addisonian pernicious anemia was correct. In all but one or two cases hospitalization was continued at least until the end of the second week of treatment. In many instances this was continued through the third week.

**Microbiologic Test** This work was done under the supervision of Mr. J. F. Roland in our Nutrition Section. The *Lactobacillus lactis* Dorner organism was handled essentially as described by Shorb<sup>3</sup> using a 42-hour incubation period.† Details of the method will be published in the near future. The results have

From the Chemical Research and Development Department, The Armour Laboratories, Chicago, Ill.

\*All samples referred to in this paper were prepared from pork liver.

†No enzymatic release of *Lactobacillus lactis* Dorner activity was attempted.

been expressed in terms of a 15 USP units per cc parenteral liver solution which had previously been assayed clinically and found to be moderately active. This standard was arbitrarily assigned a value of 75,000 *Lactobacillus lactis* Dorner (LLD) units per cc.\*

Table 1 gives a summary of the clinical data obtained, together with the total number of *Lactobacillus lactis* Dorner units administered to the patients during a two week period. Table 2 summarizes the correlation between the number of LLD units administered over a two week period and the clinical response as judged by the general criteria suggested by the Anti-Pericious Anemia Advisory Board of

\* This liver standard contains 4.9 micrograms of vitamin B<sub>12</sub> per cc as measured by microbiologic assay.

the U S Pharmacopoeia<sup>5</sup> as being important in evaluating the anti-pernicious anemia potency of liver extract preparations

The data presented in table 1 and summarized in table 2 suggest the following conclusions

1 From the limited series of cases reported upon experimental oral liver preparations, it appears that between 5,000,000 and 6,000,000 LLD units over a fourteen day period (350,000 to 450,000 LLD units daily) in the form of liver extract appear to be required to obtain an optimal hematologic, neurologic and general clinical response in cases of pernicious anemia. This amount of LLD activity appears to be required regardless of the manner in which the liver extract preparation is treated during processing

2 Although the series of cases reported using various experimental parenteral liver extracts is not large, it appears that the intramuscular injection of approximately 100,000 LLD units over a fourteen day period (representing approximately 6,500 LLD units daily) in the form of liver extract is required to obtain an optimal hematologic, neurologic and general clinical response in cases of pernicious anemia. Again this amount of LLD unitage appears to be required regardless of the manner in which, or the degree to which, liver extract is fractionated or refined

3 Taking into account the fact that the data presented are derived from a comparison of two bioassay methods (each of which has its own inherent variables), it is reasonable to conclude that there is a correlation between *Lactobacillus lactis* Dorner assay potency and human anti-pernicious anemia assay potency in liver extract preparations

#### ACKNOWLEDGMENTS

The clinical testing of liver fractions was under the supervision of the following physicians whose cooperation is gratefully acknowledged: Harold L. Alt, Northwestern University Medical School; Quinn B. DeMarsh, University of Washington Medical School; Robert A. Green, University of Minnesota Medical School; R. A. Hughes, St. Mary's Hospital, Montreal; C. M. Huguley, Emory University Medical School; Carl Johnson, St. Luke's Hospital, Chicago; Louis Limarzi, University of Illinois Medical School; Edward S. Mills, Montreal General Hospital; T. R. Smith, University of Chicago Medical School

## PERNICIOUS ANEMIA IN CHILDHOOD

REPORT OF CASE 1. SIX YEAR OLD GIRL WHO DID NOT RESPOND TO REFINED LIVER EXTRACT,  
FOLIC ACID AND VITAMIN B<sub>12</sub> IN SUCCESSIVE RELAPSES

B. R. WELLS, DAVE, M.D., RICHARD M. CHRISTIAN, M.D.,  
DONALD M. LEVY, M.D. AND LAWRENCE I. YOUNG, M.D.

**THE PURPOSE** of this paper is to present an unusual case of megaloblastic anemia in relapse in a 6 year old child who was treated successfully with vitamin B<sub>12</sub>. This case is of particular interest because the patient had exhibited similar responses to parenteral administration of refined liver extract and folic acid during previous relapses.

Megaloblastic anemia of infancy has recently been defined by Zeulzer and Ogden.<sup>1</sup> These investigators reserved this term for that group of children under 2 years of age who showed bone marrow changes identical with pernicious anemia and recovered either spontaneously or after a single course of liver or folic acid therapy.

Only a few cases of megaloblastic anemia in children requiring continuous treatment with antipernicious anemia factor have been reported. Jonsson<sup>2</sup> listed only 7 cases in addition to 2 of his own that he felt met the requirements, and Peterson and Dunn<sup>3</sup> accepted only 3. These cases have been amply reviewed by Jonsson,<sup>2</sup> Peterson and Dunn<sup>3</sup> and by Benjamin.<sup>4</sup> An additional case representing the same disease complex has been reported by Waagstein.<sup>5</sup> Prompt response followed administration of liver extract or folic acid in these cases, but response to vitamin B<sub>12</sub> in such patients has not yet been reported.

Vitamin B<sub>12</sub>, a pure crystalline antipernicious anemia factor, isolated from liver, was announced in a series of three papers<sup>6-8</sup> published in April 1948 in this country and by Smith<sup>9</sup> in England at about the same time. Spies<sup>10-12</sup> and associates demonstrated the effectiveness of vitamin B<sub>12</sub> in cases of pernicious anemia in adults, macrocytic nutritional anemia, tropical sprue and non-tropical sprue. Berk et al.<sup>13</sup> reported that vitamin B<sub>12</sub> was effective in the treatment of the neurologic manifestations in pernicious anemia. Hall and Campbell,<sup>14, 15</sup> after treating 11 patients with pernicious anemia, state that vitamin B<sub>12</sub> was as effective as liver extract in managing the hematologic and neurologic aspects of the disease. Lohby<sup>16</sup> reported that vitamin B<sub>12</sub> alone was ineffective in the treatment of megaloblastic anemia of infancy, but when small amounts of folic acid were added a response was obtained. He concluded that vitamin B<sub>12</sub> alone could not catalyze nucleoprotein metabolism to the complete stage necessary for red blood cell formation.

Bethell and his associates<sup>17</sup> have shown that B<sub>12</sub> is present in the feces of patients

From the Departments of Pediatrics and Medicine The University of Rochester School of Medicine and Dentistry Rochester N. Y.

The observations described in this paper were made under a contract with the University of Rochester Atomic Energy Project and were supported in part by the Hochstetter fund.

with pernicious anemia in relapse in approximately the same quantities as in normal individuals. Fecal extracts from a patient with pernicious anemia in relapse when given intramuscularly to an untreated case of pernicious anemia, produced significant hematologic and clinical response. Bethell states, however, that vitamin B<sub>12</sub> is ineffective in macrocytic anemia of pregnancy and the puerperium. It appears that vitamin B<sub>12</sub> may be the principal anti pernicious anemia factor in liver, although information thus far accumulated is not conclusive.

### REPORT OF CASE

M. D. unit # 189620 was born in Rochester Municipal Hospital on 4/4/42 following 9 months gestation period and a normal labor. The birth weight was 3400 grams. The cord blood Wassermann was negative. The neonatorium was not remarkable; no cyanosis, jaundice or pallor was noted. There were 4 normal siblings ages 12, 10, 8 and 3 years. The father and mother were in good health and of Sicilian extraction.

The child did well and showed no abnormalities in growth and development until the age of 16 months. In the fall of 1943 she was admitted to the Strong Memorial Hospital on three occasions because of progressive irritability, anorexia, pallor and weight loss. On each occasion marked anemia with red blood counts as low as 1.68 million and hemoglobin as low as 4.4 grams per cent were found. She was treated symptomatically and given several small whole blood transfusions. No definite diagnosis was made.

#### *Fourth Hospital Admission on 11/20/44*

**Interval History.** The patient during the six weeks between the third and fourth admissions was moderately improved for about one week, after which there was progressive return of symptoms. Lassitude and drowsiness were noted for two weeks prior to admission and edema around the eyes was noted for several days before admission.

**Physical Examination.** She was afebrile but pale, irritable and appeared chronically ill. The liver and spleen were not palpable and the neurologic examination was not remarkable. The examination was otherwise entirely negative.

#### *Laboratory. Figure 1*

**Course.** Three days after admission therapy with refined liver extract\* was started, 1 cc (15 units) weekly for 5 injections. A maximum reticulocyte response of 35 per cent was obtained on the fifth day of treatment. She was discharged on the thirtieth hospital day when the red blood cell count was 4.4 million and hemoglobin was 12.5 Gm.

The child was followed in the Out Patient Department for four months during which time she received two injections of refined liver extract. There were no complaints and the child gained 6 pounds in weight during this interval. She failed to return and was not seen for nine months until April 1945 when her symptoms recurred and it was found that the hemoglobin had fallen to 7.8 Gm. per cent. A course of six weekly injections of refined liver extract was started and in June 1945 she had no complaints, was cheerful and eating well and the hemoglobin was 13.6 Gm. per cent. She again failed to return for observation and therapy.

#### *Fifth Hospital Admission on 4/19/45*

**Interval History.** Patient did well for about five months following the liver therapy of the previous spring. Over the five months preceding the present admission she showed a gradual return of symptoms.

**Physical Examination.** The patient appeared chronically ill, was irritable and showed a yellowish sal low color to the skin. The liver was palpable two fingerbreadths below the costal margin but the spleen was not felt. Except for a soft blowing apical systolic murmur the remainder of the physical examination was negative.

**Laboratory.** Laboratory findings not included in table 1 were as follows. Vitamin A absorption and glucose tolerance tests were normal. Duodenal drainage revealed normal juices. G-1 series showed a probable deficiency pattern. The electrophoretic pattern was normal. Sickling tests were negative.

\* Reticulogen—Eli Lilly and Company

in the bone marrow are shown in figure 1. She was discharged on the fourteenth hospital day with red blood cell count of 3.7 million and hemoglobin of 12 grams per cent.

The patient is currently receiving 15 units of refined liver extract every three weeks. Clinical and laboratory findings are normal at the time of this writing.

### DISCUSSION

The similar responses to refined liver extract, folic acid and vitamin B<sub>12</sub> are illustrated in the upper three graphs of figure 1. Maturation of erythroid elements

FIG. 1.—Hematologic response to therapy with liver, folic acid and vitamin B<sub>12</sub>.

in the marrow following administration of B<sub>12</sub> is also shown graphically in figure 1 and photomicrographs of the maturing erythroid cells are shown in figure 2. The need for continuous therapy to prevent relapse is apparent in view of the five relapses that have occurred during the four years of observation.

The criteria necessary for the diagnosis of pernicious anemia in childhood according to Peterson and Dunn<sup>2</sup> are (1) macrocytic anemia, (2) arrest of maturation of bone marrow at the megaloblastic level, (3) specific response, i.e., reticulocytosis after liver therapy, (4) need for continuous therapy to maintain a continuous remission, (5) histamine resistant achlorhydria.

There is general agreement concerning the first four of these criteria, but other

the fact that a small amount of free hydrochloric acid was present in the gastric juice after injection of histamine. Prompt hematologic response was obtained following administration of refined liver extract, folic acid and vitamin B<sub>12</sub> in successive relapses.

# TUBERCULOUS SPLENOMEGALY WITH THE HYPERSPLENISM SYNDROME

## A CASE REPORT

Bj H C MEREDITH, JR, M D, J Q EARLY, M D, AND WALTER BECKER, M D

ALTHOUGH secondary involvement of the spleen in tuberculosis is quite common, the clinical picture of an enlarged tuberculous spleen with little or no tuberculosis elsewhere is rare.<sup>1-10</sup> This syndrome is often referred to as primary tuberculosis of the spleen, and was first recognized by Coley in 1846.<sup>1a</sup> The term primary tuberculosis of the spleen implied that the principal location of the disease was in the spleen which acted as a focus for the dissemination of the tubercle bacilli and was responsible for the hematologic effects. Englebreth-Holm in 1938 felt that that term was misleading, as tuberculosis of the spleen must always be secondary, and insisted it be called tuberculous splenomegaly,<sup>5</sup> a term now agreed to by most writers.

Recently there has been such a case in the University of Virginia Hospital following streptomycin-treated military tuberculosis. Although there was apparent recovery from military tuberculosis, a very marked splenomegaly developed in association with leukopenia and anemia. Following splenectomy, definite clinical improvement occurred and the blood picture returned to normal. However, six weeks postoperatively, the patient developed a fulminating tuberculous meningitis and died.

## CASE REPORT

An 18 year old white male was admitted to the University Hospital on February 8, 1948. Two months previously he had first noticed a nonproductive cough associated with a dull pain in the left chest. Three weeks before admission the chest pain became more severe and simultaneously the cough increased and became productive of small amounts of yellowish sputum. Weakness, malaise, fever and severe night sweats developed necessitating confinement to bed. The patient was seen in the Outpatient Department five days before admission and an x-ray of the chest showed only accentuation of the pulmonary markings. A shaking chill occurred two days later and hospitalization was advised. There was a 25 pound weight loss.

On admission temperature was 100.5 F, pulse 120, respiration 24, and blood pressure 120/60. The patient was pale with flushed cheeks, undernourished, and showed evidence of recent weight loss. There was a generalized lymphadenopathy of small nontender discrete nodes. Examination of the chest revealed dullness to percussion in the left base posteriorly, slightly diminished breath sounds over the right lower chest, and a few small crepitant rales in both bases. The liver was just palpable and a firm spleen edge extended 7 cm. below the costal margin. A dorsal kyphosis and scoliosis to the left were also noted.

The admission blood counts are shown in table 1. A mild anemia and marked leukopenia were present. The differential smear showed an increased number of monocytes and a normal number of platelets. The urine and Wassermann were negative. A sternal marrow examination revealed an increase in immature granulocytes. Numerous sputum examinations and cultures revealed only the usual flora. Repeated blood

From the Departments of Internal Medicine and Surgery, University of Virginia Hospital, Charlottesville, Va.

cultures stool examinations and agglutinations for typhoid tularemia, brucellosis typhus and Rocky Mountain spotted fever were negative. No abnormalities were found in the spinal fluid.

Chest roentgenograms on admission revealed multiple milary opacities throughout the lungs and their appearance over a five day period strongly suggested milary tuberculosis. Abdominal x-ray films disclosed a mass in the left upper quadrant which was thought to be the spleen as well as evidence suggesting an enlarged liver.

*Course.* During the early period of hospitalization the temperature ranged between 100 F and 104 F and the patient's condition became more precarious daily. Penicillin was started empirically without effect.

During the second week gastric washings were found to be positive for acid fast bacilli on two occasions. A tuberculin skin test (1:1000) was negative and histologic examination of a lymph node biopsy showed only chronic lymphadenitis. Repeat chest x-rays demonstrated further increase in the lung markings and a progression of the soft generalized milary infiltration. The diagnosis of acute milary

TABLE 1—Hematologic Data during the Patient's Illness before and after Splenectomy

12-1-48	4.9	11	8100		72	17	9		2			34 days postop.

tuberculosis was considered established and streptomycin was begun in a dosage of 2 Gm. daily on the ninth day.

By the thirteenth hospital day the fever began to exhibit a downward trend. Five days later chest films showed further spread of the generalized milary opacities but the typical progressive picture of milary tuberculosis appeared altered and this was attributed to the use of streptomycin. Consequently the dose of this antibiotic was increased to 3 Gm. daily. He improved slowly and by the thirty-seventh day he was afebrile. The dosage of streptomycin was then decreased to 2 Gm. daily. Chest x-rays at this time demonstrated a beginning diminution of the milary process.

Throughout the rest of his hospital stay he remained afebrile and gained 14 pounds with notable symptomatic improvement. However the spleen remained enlarged and repeated blood studies showed a persistent leukopenia and anemia (table 1). Another tuberculin skin test was done and was found positive in the 1:10,000 dilution. Further chest roentgenograms taken on the sixty-second hospital day revealed no evidence of tuberculosis. On April 14, 1948, after 66 days of hospitalization he was discharged in an asymptomatic state to a tuberculosis sanatorium for further care. He had received a total of 107 grams of streptomycin.

While in the sanatorium although streptomycin was not continued he was afebrile, and gained 22 pounds in the next three months. Fever recurred in July and a downhill course ensued with the loss of 18 pounds in the next two months. Frequent examinations of the spleen showed progressive enlargement. Associated with this was an increase in the leukopenia and anemia (table 1).

When readmitted to the University Hospital on September 27, 1948 for further studies the patient

appeared chronically ill and had a temperature of 100 F. A smooth, slightly tender spleen could be palpated extending almost to the pubic symphysis and well across the midline of the abdomen. Blood studies again revealed an anemia, marked leukopenia, and granulocytopenia (table 1). The sternal bone marrow was hyperplastic. Bleeding time, clotting time, clot retraction, and tourniquet tests were normal. Liver function studies were normal. Urine and stool examinations were again negative. Roentgenograms of the skull, spine, hands, pelvis, and femora were negative. During this hospitalization of six days, his temperature ranged from normal to 102 F. A diagnosis of tuberculous splenomegaly was made on the basis of the history of miliary tuberculosis, fever, splenic enlargement, and the findings in the blood.

FIG. 1. OUTLINE OF THE SPLEEN PRIOR TO SPLENECTOMY

Splenectomy was advised. After receiving 1500 cc. of whole blood he was discharged to the sanatorium for further streptomycin therapy before surgery.

He remained in the sanatorium twenty-four days and during the latter twenty-one he was afebrile. However, he continued to lose weight and the splenic enlargement increased.

On October 26, 1948, he was readmitted to the University Hospital for splenectomy. Physical examination and the laboratory findings were as before. On the following day a laparotomy was performed and a very large spleen was found, filling the entire left side of the abdomen and displacing the viscera to the right. The inferior pole of the spleen extended below the sacral promontory and the capsule was extensively adherent to the surrounding structures. The liver was slightly enlarged but appeared normal. The spleen (fig. 2) was removed without difficulty and was found to weigh 3363 grams. It was smooth with a purplish grey color and had a fairly soft consistency.

On histologic examination the architecture was almost entirely replaced by tubercles with a few areas of caseation. Tubercle bacilli were demonstrated in the spleen by acid fast stains. The hilar lymph nodes were also involved with tubercles. Emulsified spleen injected into guinea pig resulted in the development of typical caseous tuberculous lesions and acid fast organisms were demonstrated in the tissues.

Within twenty four hours after the operation there was a striking increase in the white cell and platelet counts (table 1). The patient's postoperative course was uneventful except for a moderate fever. Streptomycin was continued and penicillin was added for prophylactic purposes. He was discharged to the sanatorium on the ninth hospital day for further treatment.

For the first six weeks in the sanatorium he was asymptomatic, afebrile, and gained weight. Streptomycin was discontinued at the end of four weeks. The hematologic studies remained normal and follow-up chest x-rays showed no evidence of military tuberculosis. However, during the seventh week he began

FIG. 2. CROSS SECTION OF THE SPLEEN

to run a fever and developed a stiff neck. Spinal fluid studies confirmed the clinical impression of tuberculous meningitis. Despite the resumption of streptomycin intramuscularly and intrathecally he went rapidly downhill and died within a week.

*Autopsy.* Postmortem examination revealed a healed primary tuberculous lesion at the periphery of the left lower lobe of the lung and military tuberculosis of the lungs, liver, lymph nodes and meninges. These lesions were evident grossly and microscopically and tubercle bacilli were present in smears taken from the meninges. In the cortex of the left temporal lobe there was a 5 mm area of caseation with overlying meningeal adherence. This was probably the direct source of the meningeal infection. Death was undoubtedly due to tuberculous meningitis.

### DISCUSSION

The military tuberculosis in this case at first responded dramatically to streptomycin therapy. Despite the use of this drug, the spleen, which previously had been moderately enlarged, gradually increased in size until it occupied most of the abdomen. Along with this was the development of a marked leukopenia and anemia. Three months after streptomycin was discontinued, fever returned asso-

ciated with a progressive loss of weight. A diagnosis of tuberculous splenomegaly was made and the antibiotic therapy resumed. His temperature fell to normal but he continued to lose weight and go downhill. Consequently, a splenectomy was done with the prompt reversion of the blood picture to normal and notable improvement of the patient for six weeks. However, during the seventh postoperative week he developed a fulminating tuberculous meningitis and succumbed a few days later.

Although Winternitz in 1912 felt that the blood picture in primary tuberculosis of the spleen was not constant, of the 51 cases that he collected, 42 per cent had an anemia, and 25 per cent had polycythemia.<sup>1</sup> In this series only 19 had white cell counts and 27 per cent of these had a leukopenia of 5,000 or less.<sup>1</sup> He also noted purpura in 2 cases. In the twenty years following this classic exposition, isolated reports appeared noting the association of this disease with leukopenia, anemia, thrombocytopenia, and purpura.<sup>2-4</sup> In 1931, Price and Jardine described 4 cases resembling Banti's syndrome which were diagnosed at operation or by autopsy as primary tuberculosis of the spleen.<sup>4</sup> Englebreth-Holm in 1938 after reviewing the literature and studying 4 cases of splenomegaly following military tuberculosis, observed its frequent association with anemia, leukopenia, and other evidences of bone marrow inhibition.<sup>5</sup> He concluded that tuberculous splenomegaly caused inhibition of the emission or the maturation of the blood cells in the bone marrow. In 1941, Weiner and Carter reviewed the previously reported cases of thrombocytopenia and purpura associated with tuberculous splenomegaly and added another.<sup>6</sup> The entire subject of the hemopoietic effect of this splenic disorder was reviewed briefly in 1942 by Brown, Mason, and Lucia and again by Dietz in 1946. To date less than 100 cases have been published. The occurrence in this type of splenic tuberculosis of leukopenia, anemia, and thrombocytopenia, singly or together, fits well into Dameshek's recent theory of selective and total types of hypersplenism. Dameshek postulated that the development of the one or more cytopenias in hypersplenism is due to abnormal or excessive splenic activity causing bone marrow inhibition.<sup>14, 15</sup> It is also consistent with Doan and Wright's concept of excessive destruction of blood cells by an abnormal spleen.<sup>16</sup>

The diagnosis of tuberculous splenomegaly is difficult and usually is made at the operating table or on postmortem examination. It is found most commonly in the 20 to 40 age group.<sup>2, 4, 10</sup> and the diagnosis depends on such features as a history of previous tuberculosis or exposure, splenomegaly, evidences of tuberculosis in other organs, moderate fever, evidences of bone marrow inhibition, and a downhill course. Occasionally calcium deposits can be demonstrated in the spleen by x-ray.<sup>6, 7, 12</sup> Splenic puncture with culture for the tubercle bacillus is considered of diagnostic value by some, for the organisms are quite plentiful in this organ.<sup>6, 7, 10</sup> This type of splenomegaly should be differentiated from Banti's syndrome, leukemia, lymphosarcoma, Hodgkin's disease, cirrhosis of the liver with splenomegaly, malaria, certain parasitic infections, thrombosis of the splenic vein, agnogenic myeloid metaplasia of the spleen, Felty's syndrome, and others.

Splenectomy, by unanimous agreement, is the treatment for this disorder, for

the outcome without it is generally considered to be invariably fatal<sup>1 2 4 5 10 11</sup>. The object is the elimination of the focus of dissemination of tubercle bacilli by hematogenous spread, to remove the inhibiting effect on the bone marrow, and to relieve the discomfort caused by the splenic enlargement<sup>5 10 12</sup>. In some instances the patients may not survive because of tuberculosis in other organs<sup>1</sup>. With the addition of streptomycin the prognosis should be improved. The use of streptomycin in this case did not eliminate the need for surgery.

The pathology of these spleens is quite interesting. The majority are usually huge, weighing from 1000 to 3000 grams<sup>1 5 7 9 13</sup>. The spleen in this case weighed 3,363 grams and is one of the largest reported. On macroscopic examination tubercles may or may not be seen, while caseation or abscess formation is extremely rare<sup>1 4 12 13</sup>. The histopathologic appearance is that of a very cellular pulp with numerous partly confluent miliary tubercles with little or no necrosis and only a few small malpighian bodies<sup>1 5 7 10 11</sup>. The splenomegaly is secondary to proliferation of the reticulum cells of the pulp and to the presence of tuberculous foci<sup>5</sup>.

Had the correct diagnosis been made earlier in the case reported and had splenectomy been done within the first or second month after the notable response to streptomycin, the outcome might have been different. The spleen by remaining in situ with its infection could have acted as the focus for reinfection and establishment of other foci after the organism had become resistant to streptomycin.

### SUMMARY

A case of tuberculous splenomegaly with leukopenia and anemia following miliary tuberculosis has been presented. Splenectomy was required after streptomycin failed to control the cytopenias, progressive emaciation, and splenic infection. However, following what appeared to be six weeks of marked improvement, the patient developed a fulminating tuberculous meningitis and died.

### ACKNOWLEDGMENT

The authors are indebted to Dr. Byrd S. Leavell for his suggestions in the preparation of this paper.

## IRON METABOLISM

THE PHYSICO-CHEMICAL REGULATION OF SIDEREMIA *S Neukomm* (University of Zurich Med School Med Polyclinic) *Acta haematol* 213 1949

Exhaustive experimental investigation leads the author to the conclusion that the fixation of iron on proteins depends mainly on the pH of the medium. The serum albumin fraction contains most of the serum iron. Hence in vivo a decrease in serum iron parallels a decrease in albumin. At the same time the erythrocyte sedimentation rate rises. There exists a mathematical correlation between the quantity of serum albumin, the sedimentation rate and the blood level of serum iron. (See also C. B. Lawell *Acta physiol Scandinav* 24 suppl 46 1947; C. E. Rath and C. A. Finch *J Clin Investigation* 23 79-85 1949; G. E. Cartwright and M. M. Winterbe *J Clin Investigation* 23 86-98 1949)

IRON METABOLISM AND HEMOCHROMATOSIS *S Granick* From the Laboratories of The Rockefeller Institute for Medical Research New York N Y *Bull New York Acad Med* 25 403-428 1949

This review includes a comprehensive discussion of the iron compounds of the body and their properties, the mechanisms concerned in the regulation of iron absorption by the gastrointestinal mucosa, and the possible abnormalities in iron metabolism which may lead to the development of hemochromatosis.

The author's own hypothesis of the regulation of iron absorption assumes the existence of a gradient of reduction in the mucosal cell, e.g. that part of the cell nearest to the lumen of the gut is less reducing for ferric iron and that portion closest to the blood stream has a higher reducing ability. Two regulatory mechanisms, however, are probably involved. One is the determination of the amount of ferrous iron moving into the cell by a mucosal bloc which is related to the ferritin content of the mucosal cells. The other concerns the reducing ability of the cell wherein the amount of ferrous iron entering the blood stream depends on the relative redox level of the cell which in turn is a function of the amount of oxygen supplied by the blood stream.

Evidence is presented which suggests that the metabolic defect in hemochromatosis does not reside in those factors concerned with the mucosal bloc but rather is related to a greater reducing tendency of the cell for iron which permits more iron to enter the blood stream. Such a state could arise from either an increase in the effectiveness of reducing enzymes or a decrease in effectiveness of oxidizing enzymes. (See also S. Frandsen *Acta med Scandinav* 125 186-201 1947)

H W B

IRON DEFICIENCY STATES AND THEIR THERAPY WITH NEW FERROUS SALTS *B Jasinski* From the Medical Department of the Cantonal Hospital Winterthur (Switzerland) *Helv Med Acta* 26 67 1949

The author has made investigations especially with ferrous gluconate and ferrous formate. He found that small peroral doses of iron (44 mg) did not substantially alter the serum iron level of normal as well as of anemic subjects. Even larger doses of iron very rarely influenced the serum iron level of normal persons. It is the author's opinion that the hydrochloric acid in gastric secretion is of little significance for the absorption of iron preparations, yet that it plays an eminent rôle in the utilization of the iron in the food. The absorption rate of iron compounds may be assumed only in anemics. In cases

of infectious anemias and of malignant tumors the absorption of iron is inhibited i.e. we find the same rates as in normal persons. Yet there are some cases of infectious anemias that respond readily to high doses (470 mg. iron). In cases of idiopathic chronic hypochromic anemia a well tolerated iron compound is necessary. The ferrous gluconate fulfills this requirement remarkably well.

## ANEMIA

THE ANEMIC STATES THEIR CAUSES AND TREATMENT. C. A. Dean and C. S. Wright. From the Division of Medical Research, Department of Medicine, Ohio State University, Columbus, Ohio. *M. Clin. North America* 33: 541-560, 1949.

The authors briefly discuss normal erythropoiesis and erythrophagocytosis, the anemias of central bone marrow origin, and finally anemias due to excessive peripheral demand (loss or destruction). Under the last subject the views of these authors on hypersplenic syndromes are discussed in some detail with illustrative examples.

G E C

THE EFFECT OF VITAMIN B<sub>12</sub> ON THE ANEMIA AND COMBINED SYSTEM DISEASE OF ADDISONIAN PERNICIOUS ANEMIA. S. R. Muttar, A. McBride and R. Tat. From the Division of Medicine of the University of California Medical School, San Francisco, Calif. *California Med.* 71: 23-27, 1949.

A study of the effect of the parenteral administration of vitamin B<sub>12</sub> on the course of 8 patients with Addisonian pernicious anemia was made. Following an initial dose of 25-50 micrograms, all patients exhibited reticulocytosis within 48 hours and peak response at about 96 hours following injection. In only 2 were secondary reticulocyte responses induced by a subsequent injection. Although maximal reticulocytoses as indicated by L. J. 22.5 formula were not obtained, the immediate conversion of megaloblastic bone marrow to a normoblastic picture and the return of erythrocytes and hemoglobin to normal levels within sixty days indicated a satisfactory remission. The authors recommend average maintenance injections of vitamin B<sub>12</sub> in the amount of 30-50 micrograms at intervals of one month. Paresthesias and other symptoms relative to early and moderately advanced combined system disease were found to disappear or be ameliorated. In a single case sensitive to refined liver, no sensitivity to vitamin B<sub>12</sub> was noted. Preliminary observations on a group of patients whose combined system disease had persisted in spite of large doses of liver extract indicated some subjective but no objective improvement in their condition following the administration of vitamin B<sub>12</sub>.

W N V

TREATMENT OF PERNICIOUS ANEMIA WITH CRYSTALLINE VITAMIN B<sub>12</sub>. R. West and E. H. Reissner, Jr. From the Department of Medicine, College of Physicians and Surgeons, Columbia University and the Fourth Medical Division, Bellevue Hospital, New York, N. Y. *Am. J. Med.* 6: 643-650, 1949.

Eleven cases of Addisonian pernicious anemia treated with parenteral vitamin B<sub>12</sub> are reported. All showed a satisfactory hematologic remission and 5 patients with combined system disease showed neurologic improvement. Different and in several cases amended dosage schedules were employed and from these several observations it was concluded that the effective parenteral dose was slightly less than one microgram daily. This approximation of a minimal effective dose is borne out by other similar studies. Any evaluation of the effectiveness of an average daily dose must, however, take into consideration the frequency and size of the individual doses.

H W B

OBSERVATIONS ON THE MACROCYTIC ANEMIA ASSOCIATED WITH PREGNANCY. T. D. Spies. From the Department of Nutrition and Metabolism, Northwestern University and the Hillman Hospital, Birmingham, Ala. *Surg. Gynec. & Obst.* 89: 76-78, 1949.

Six patients with macrocytic anemia associated with pregnancy were studied within a few weeks after delivery. The reportedly satisfactory clinical and hematologic response to folic acid is illustrated by one case report.

The author stresses the importance of realizing an association between this type of anemia in the

mother and the development of megaloblastic anemia in the infant and states that both of these can usually be prevented by treatment of the mother with folic acid during the late stages of pregnancy  
H W B

ANTI ANAEMIA ACTIVITY OF FAECAL EXTRACT FROM PERNICIOUS ANAEMIA PATIENT *S T E Callender B J Mallett G H Spray and G E Shaw* From the Nuffield Department of Clinical Medicine Oxford, and the Evans Biological Institute Runcorn Cheshire England *Lancet* 2: 57 1949

Two hundred grams of wet feces from a patient with untreated pernicious anemia were subjected to a papain digest and phenolic extraction. *L. lactis* Dorner assay of the extract showed 1 microgram per ml equivalent of B<sub>12</sub> activity. Five ml of extract given daily for five days to a second patient with untreated pernicious anemia resulted in an optimal therapeutic response. Chromatography of the extract gave a chromatogram closely resembling those shown by purified liver extracts

S C.

EXPERIMENTAL MACROCYTIC ANAEMIA IN THE RAT TREATED WITH PURIFIED LIVER EXTRACT PTEROYL-GLUTAMIC ACID AND VITAMIN B<sub>12</sub> *D G Cameron S T E Callender G M Watson and L J Wills* From the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford England *Nature* 164: 188 1949

Twenty six rats made anemic by the formation of a cul de sac in the small intestine (see *Lancet* 2: 404 1948 *Blood* 4: 803 1949) were divided into four groups: a control group and groups treated parenterally with Anahaemin, pteroylglutamic acid and vitamin B<sub>12</sub> respectively. There was a significant increase in survival time with pteroylglutamic acid but not with Anahaemin or B<sub>12</sub>. Five of 6 animals treated with P.G.A. showed a hematologic remission. Two from each of the Anahaemin and B<sub>12</sub> groups of 7 and 6 animals also had a remission. The impression was that this was not fortuitous but as spontaneous remissions occurred in the control group the effect of liver extract and B<sub>12</sub> was not clear cut

S C.

NUTRITIONAL MACROCYTIC ANAEMIA IN TEMPERATE ZONES *J Rubin and C D Calnan* *Brit M J* 1: 1079-1081 1949

A case of nutritional macrocytic anemia in a mentally subnormal woman of 56 is described. The anemia failed to respond to treatment with 2 ml Anahaemin daily for ten days followed by 4 ml Flexan crude liver daily for five days but a good response was obtained with folic acid

S C.

MEGALOBlastic ANAEMIA IN COELIAC DISEASE TREATED WITH FOLIC ACID *M L Thomson H W Dalton and Vera K Wilson* From the Royal Manchester Children's Hospital *Lancet* 2: 238-240 1949

This is a detailed report of the two cases of coeliac disease associated with megaloblastic change in the bone marrow already briefly described in 1946 (Dalton et al. *Lancet* 2: 652, 1946). Treatment with folic acid resulted in general improvement with reversion to normoblastic marrow. One child remained well after discharge on 5 mg folic acid twice weekly but the other relapsed. A second relapse later led to complicating infection and death

S C.

LACTOBACILLUS LACTIS DORNER FOR THE ASSAY OF VITAMIN B<sub>12</sub> *G E Shaw* From the Evans Biological Institute Runcorn Cheshire England *Nature* 164: 186-187 1949

A technic is described for L. Dorner assay of B<sub>12</sub> in liquid medium (For details the original article should be studied). An identical shape of dose response curve is obtained with all types of liver extract, crystalline B<sub>12</sub> and Thymidine or a blend of any of these. Digesting liver with papain does not alter the shape of the curve

S C.

THE EFFECT OF ORAL THERAPY WITH COBALTOUS CHLORIDE ON THE BLOOD OF PATIENTS SUFFERING WITH CHRONIC SUPPURATIVE INFECTION *J C Robinson G W James III and R B Lark* From the Medical

Nutrition Laboratory, Department of the Army and the Department of Medicine, University of Illinois College of Medicine, Chicago, Illinois. *New England J Med* 240: 749-753, 1949

Nine patients with prolonged suppurative infections were treated for two to eleven weeks by the oral administration of 20 to 60 mg. of cobaltous chloride daily. This uniformly resulted in a reticulocytosis, an increase in the circulating erythrocyte hemoglobin and packed red cell concentration of the blood and an increase in the total red cell mass. This is a clean-cut demonstration of the stimulating action of cobalt on the bone marrow as has previously been demonstrated in animals.

The studies of Heilmeyer, Cartwright and Wintrobe and others indicate that the primary fault in the anemia of infection is a retarded rate of hematopoiesis. The clinical demonstration that cobalt acts in the opposite direction to counteract this anemia still leaves open the fundamental question: is the anemia of infection harmful to the individual or is it a useful compensatory device to conserve metabolic energy during a period of emergency? More evidence must be accumulated before it will be possible to pass opinion on the desirability of cobalt therapy for the anemia of infection.

C A F

ERYTHROPOIETIC EFFECT OF COBALT IN PATIENTS WITH OR WITHOUT ANEMIA. *L. Berk, J. H. Barbenel and W. B. Castle*. From the Thorndike Memorial Laboratory, Boston City Hospital and Harvard Medical School, Boston, Massachusetts and the Memorial Hospital for Cancer and Allied Diseases, New York. *N. Y. New England J. Med.* 240: 754-761, 1949.

Cobaltous chloride ( $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$ ) was administered to 61 patients by mouth. In 7 convalescent and 8 psychotic patients, consistent reticulocytosis and elevation of hemoglobin and red count above control levels were observed. The average reticulocyte peak on a dose of 300 mg./day was 4.9 per cent and occurred between the fourth and tenth day. This dose of cobaltous chloride was not tolerated by 12 patients with pernicious anemia in remission. A good erythropoietic response was observed in 2 of 5 patients with infection. Five patients with refractory anemia and hyperplastic bone marrow gave no response. Sixteen patients with anemia due to leukemia or lymphoma were treated. There was no response in 13 of the patients. In 3 others, evidence was equivocal because of therapy of the underlying disease. One of 2 patients with hypochromic anemia due to iron deficiency and one patient with Cooley's trait responded while a patient with the anemia of liver disease was not affected. Two patients with chronic nephritis could tolerate the drug for only a few days but showed no reticulocyte response.

No serious toxic manifestations were observed but gastrointestinal symptoms of nausea and vomiting were present in 37 of the 61 patients.

It is apparent from this and other studies that cobalt provides an additional stimulus to the marrow for hematopoiesis. One might generalize from these observations that the action of cobalt is most conspicuous when the bone marrow is not under a great stimulus before treatment. As stated by the authors, the possibility that the erythropoietic action depends upon a fundamental alteration of tissue respiration indicates the need for further studies of chronic toxicity in animals.

C A F

## POLYCYTHEMIA VERA

OSLER'S CHRONIC CYANOTIC POLYCYTHEMIA WITH SPLENOMEGALY. *M. M. Wintrobe*. From the Department of Medicine, University of Utah College of Medicine, Salt Lake City, Utah. *Bull. Johns Hopkins Hosp.* 85: 75-86, 1949.

An excellent discussion of the historical aspects, clinical features, pathologic physiology and pathogenesis of polycythemia vera with particular reference to the contributions of Sir William Osler is presented. Brief mention of available therapy is made. Of particular interest is the critical evaluation of the various concepts of the pathogenesis of the condition and particularly those concepts relating to the role of anoxia. The author, while regarding the subject as an open one, is inclined to favor the view that erythremia is similar in its pathogenesis to leukemia and is not attributable to the influence of anoxia on the bone marrow.

W N V

THE CONTROL OF POLYCYTHEMIA BY MARROW IRRADIATION. A TEN YEAR STUDY ON 172 PATIENTS. *J. H.*

*Laurence* From the Division of Medical Physics and Donner Laboratory University of California Berkeley Calif J A M A 141 13-18 1949

Of 172 patients with various forms of polycythemia radioactive phosphorus was used in the treatment of some 121 in whom the diagnosis of idiopathic polycythemia (polycythemia vera) could be made. This report details the results of this form of treatment ten years after its inception.

In general the results of treatment were very satisfactory, with good relief of symptoms and signs. Of all patients treated 48 per cent required only one course of treatment of those treated during the first five years 28 per cent had only one such course and some required no further therapy for four to as long as eight years. Among other things the spleen regularly became smaller or even impalpable following treatment. Some 35 per cent of patients with polycythemia in whom the blood pressure was initially elevated showed a fall of blood pressure after  $P^{32}$  therapy. Some 70 per cent of patients with initial leukemoid blood counts showed disappearance of this feature following  $P^{32}$ .

There was no evidence of an increase of leukemia following the use of  $P^{32}$  of the 21 deaths in this series 5 (about 4 per cent) were due to leukemia. This complication was no more frequent in this group than in polycythemic patients who are untreated or treated with other methods (Fowler's solution  $\gamma$  ray, etc.).

It was of interest that thromboses seemed to be reduced following the use of  $P^{32}$  they occurred in 4.2 per cent of patients following therapy as compared with 25 per cent before treatment. Phlebotomies alone did not reduce the incidence of thromboses to this degree.

Finally the average duration of life following diagnosis was 17 years. The average age at diagnosis in this group was 50.7 years, at death 67 years. The author points out therefore that with this form of treatment the life expectancy of the newly-discovered polycythemic is as good as that of the diabetic with insulin or that of the pernicious anemia patient with liver extract. The use of radioactive phosphorus is recommended as the ideal form of treatment of polycythemia vera at the present time.

S. E.

## LEUKOCYTES

*LIVER FUNCTION DURING INFECTIOUS MONONUCLEOSIS* J. W. Brown, J. L. Sims, E. White and J. E. Clifford. From the Departments of Medicine and Preventive Medicine and Student Health University of Wisconsin Medical School Madison Wisc. Am J Med 6 321-328 1949.

Liver function tests were performed at random or in series during the course of infectious mononucleosis in 83 patients between the ages of 17 and 34. Tests included icterus index, qualitative urine urobilinogen excretion, cephalin cholesterol flocculation, thymol turbidity, prothrombin time and bromsulphalein dye retention. One or more of these tests were abnormal in 75 of the cases. The most frequently abnormal test was the cephalin cholesterol flocculation which became positive early and for a significant length of time in nearly all cases tested in series. Since it was positive more uniformly than the heterophile antibody determination it was considered a valuable diagnostic aid whenever infectious hepatitis of virus etiology could be excluded. The next most frequently abnormal test was the thymol turbidity. Abnormalities in the icterus index, urobilinogen excretion and bromsulphalein retention were also detected in a significant number of cases.

This and other studies indicate that nearly all patients with infectious mononucleosis will demonstrate abnormal liver function at some time during the course of illness.

The authors comment on the difficulty in differentiation between infectious mononucleosis and infectious hepatitis, the lack of correlation between abnormalities in liver function and duration of symptomatology in infectious mononucleosis and the need for further study of these patients particularly after recovery. Until the clinical significance of these changes in liver function is known it is suggested that patients with infectious mononucleosis be placed on the same regimen recommended for patients with infectious hepatitis.

H. W. B.

*A TRANSPLANTABLE SPLENIC TUMOR RICH IN MAST CELLS. OBSERVATIONS ON MAST CELLS IN VARIED NEOPLASMS* T. Bali and J. Farth. From the Branch 10 Laboratories of Veterans Administration Hospital Dallas, Texas. Am J Path 25 605-625 1949.

The present investigation was prompted by the finding of numerous mast cells in and about a spontaneous epithelioid-like reticulum cell splenic neoplasm in mice. No relationship could be established between neoplastic and mast cells. Miscellaneous neoplasms with the exception of some leiomyomas were in general free from mast cells. Apparently some tumors either stimulate mast cell proliferation or attract mast cells. This may be brought about by some substance present in the tumor or by a metabolite of the tumor cells. These suggest additional experimentation with subcutaneous injections of cell free extracts of certain tumors. Recent histochemical evidence links mast cell function with production of the ground substance of connective tissue and the blood clotting mechanism.

O P J

EVALUATION OF METHOD OF ENUMERATING STERNAL MARROW EOSINOPHILS *Philip Pizzolatto* From Clinical Laboratory Service Veterans Administration Hospital Department of Pathology Charity Hospital of Louisiana and Louisiana State University School of Medicine New Orleans La. *Am J M Technol* 25: 213-216 1949

The author evaluates the various methods of counting marrow eosinophils—chamber methods, direct smear, stained sections. A combination of the Levy-Newbauer chamber method with the use of May-Grunwald-propylene glycol as diluent plus the direct smear is recommended. Variations with any method even from a single procedure are appreciable.

W N V

THE LYMPHOCYTE STUDIES ON ITS RELATIONSHIP TO IMMUNOLOGIC PROCESSES IN THE CAT *C G Craddock Jr W N Valentine and J S Laurence* From the University of Rochester School of Medicine and Dentistry and the Department of Medicine of the Strong Memorial and Rochester Municipal Hospitals Rochester N Y *J Lab & Clin Med* 34: 158-177 1949

An experimental approach is presented for the study of the antibody content of lymphocytes collected from the thoracic duct lymph of cats. Using the technic described and typhoid vaccine as an antigen, no antibody could be detected within extracts of washed lymphocytes. Comparative titrations of the relative antibody content of lymph fluid free of cells and lymph containing large numbers of lymphocytes which were artificially lysed in order to release their protein content into the surrounding lymph fluid also failed to indicate the presence of any antibody within the lymphocytes. Exposure of the animals to x-ray did not significantly alter the antibody content of the cell free lymph fluid. Administration of large doses of adrenal cortical hormones failed to cause any significant alteration in the antibody content of cell free lymph fluid.

G E C

## LEUKEMIA AND MALIGNANT LYMPHOMA

TREATMENT OF CHRONIC FORMS OF MALIGNANT LYMPHOMAS AND LEUKEMIAS *L F Greer* From the Memorial Hospital for the Treatment of Cancer and Allied Diseases New York N Y *M Clin North America* 33: 527-540 1949

This is an extremely well written, easily readable general discussion on the subject of treatment of chronic forms of malignant lymphomas and leukemias. The author discusses therapy from the simple general approach of (1) the early, strictly localized disease, (2) the intermediate stage of spread of the disease, and (3) the stage of marked generalization of the disease. Individualization of treatment is stressed. Such therapeutic agents as nitrogen mustard, x-ray, urethane, arsenic, radioactive phosphorus, benzol, and folic acid antagonists are considered. The author again expresses his encouraging belief that adequate early treatment of a localized early process may offer hope for cure.

G E C.

TREATMENT OF MALIGNANT DISEASE WITH NITROGEN MUSTARD *N B Kottick, A R Pajon, M H Fisher and D K Adler* From the Second Medical Service Mount Sinai Hospital New York N Y *Ann Int Med* 30: 974-1003 1949

The authors add 64 more cases treated with nitrogen mustard to the literature. They include 13 cases of Hodgkins disease, 4 of chronic lymphatic leukemia, 2 of chronic myelogenous leukemia, 8 of lympho-

sarcoma 10 carcinomas of the lung and other miscellaneous malignancies. Many of their cases had been treated with x ray prior to mustard therapy. Data regarding the individual cases is effectively presented in tabular form. Conclusions are essentially the same as reported by others.

C.A.F.

ADVANCES IN TREATMENT OF MALIGNANT DISEASE. *C. P. Rhoads*. From the Memorial Hospital Center for Cancer and Allied Diseases, Sloan Kettering Institute, New York, N. Y. *Bull. New York Acad. Med.* 25: 271-284, 1949.

The experimental use of folic acid conjugates and folic acid antagonists in the treatment of neoplastic diseases is briefly reviewed. It is pointed out that while the status of chemotherapy of malignant disease remains essentially unchanged, a very real step has been made toward our understanding of the pathologic physiology of neoplasms. It is entirely conceivable that with further investigation of nucleic acid metabolism more effective compounds with a far more selective effect on neoplastic tissue may be found.

H.W.B.

## BLOOD COAGULATION AND HEMORRHAGIC DISEASE

THROMBOPENIA AND INCREASED CAPILLARY FRAGILITY IN HEPATIC DISEASE. *F. B. Whitsett, Jr. and A. M. Snell*. From the Division of Medicine, Mayo Clinic, Rochester, Minn. *J. A. M. A.* 140: 1071-1076, 1949.

In a study of 70 consecutive cases of various forms of liver disease, the authors noted the frequent occurrence of a hemorrhagic diathesis in those patients with parenchymatous liver disease (hepatitis, cirrhosis), whereas hemorrhagic phenomena were rare in non-parenchymatous hepatic disorders (stone stricture, carcinoma of bile ducts or pancreas). The hemorrhagic manifestations they found were not due solely or necessarily to hypoprothrombinemia, but often to thrombocytopenia and to increases in capillary fragility. They therefore studied the occurrence of thrombocytopenia and increased capillary fragility in their 70 cases: of the 29 with extrahepatic jaundice, only 4 showed these abnormalities; of the 41 patients with hepatitis or cirrhosis, 37 showed a reduction in platelets, increased capillary fragility, or both. These findings could not be correlated with hypoprothrombinemia or with jaundice.

Few data unfortunately are presented to explain these findings. What bone marrow punctures were done showed active marrows and megakaryocytes in adequate numbers; there is no note as to platelet formation from the megakaryocytes. No data are given as to other bleeding tests beyond the generalization that, usually, the bleeding time was prolonged, the coagulation time normal or slightly prolonged, and the clot retraction poor. The authors comment that the associated hypoprothrombinemia made these tests difficult to interpret, is strange. Nor can one accept the statement that the bleeding in liver disease may so often simulate that of idiopathic thrombocytopenic purpura; that every case of the latter disorder should be suspected of being thrombocytopenia secondary to liver disease (even to the point of liver biopsy) till disproven.

The data in this report, however, emphasize that the bleeding of certain patients with liver disease may be due not to a reduction of prothrombin, but to thrombocytopenia and capillary defects. The mechanism for these alterations in blood and circulatory system and the possible role of hypersplenism, are not discussed.

S.E.

HEMOPHILIA LIKE DISEASE IN WOMEN. *J. S. Hewlett and R. L. Haden*. From the Division of Internal Medicine, the Cleveland Clinic and the Frank E. Bunts Educational Institute, Cleveland, Ohio. *J. Lab. & Clin. Med.* 34: 151-157, 1949.

Two female patients with a clinical picture of hemophilia are presented. The outstanding characteristic was a prolonged coagulation time of the blood. The coagulation time of recalcified plasma was positive in both patients. When normal citrated plasma was added to blood from one of the patients, the coagulation was markedly accelerated. Tiselius protein fractionation revealed a definite abnormality in the alpha globulins in one patient and suggestive but not conclusive evidence of an abnormality in the

wound patient. In these two patients the defect was similar to that found in hemophilia but the authors are careful to call this "hemophilia like disease" and suggest that an acquired change in the plasma protein pattern might be the basis for the coagulation defect.

G E C

CHANGES IN THE PROTHROMBIN TIME INDUCED BY METHYLXANTHINES. ROLE OF THE PLASMA COFACTOR OF THROMBOPLASTIN. *F. Herrate*. From the Chemical Laboratory, School of Dentistry, University of Chile, Santiago, Chile. Arch. Biochem. 22: 345-352, 1949.

The influence of caffeine, theobromine, theophyllin and sodium benzoate on the prothrombin time of rabbits was studied, and these substances were found to shorten the prothrombin time. These results can be observed in rabbit plasma only if the latter is diluted to 5-10 per cent. If dilutions are made with human fresh plasma treated with  $Al(OH)_3$  or with fibrinogen solutions, care must be taken to make certain no thromboplastin cofactor is present in the diluent. The authors believe that these results are produced by an increase of the thromboplastin cofactor (? synonymous with Factor V [Owren] and AC-globulin [Seegers]) associated with the administration of these drugs.

THE CONTROL OF DICUMAROL THERAPY. *J. H. Olsen*. From the Department of Surgery, Presbyterian Hospital of the City of Chicago, affiliated with the University of Illinois College of Medicine, Chicago. Ill. Am. J. M. Sc. 21: 427-437, 1949.

Ninety-nine patients were treated with dicumarol. Fifty per cent of these were treated as outpatients. One-stage prothrombin methods (whole plasma, 12.5 per cent and 5 per cent plasma) were compared with the two-stage method. Wide variations between the methods were noted. With the two-stage method it was possible to maintain the prothrombin level accurately within a desired range over a period of months, with a maximum variation of 15 per cent. The one-stage method was found to be of value in estimating the summation of clotting factors in an individual blood, particularly at a time when the prothrombin as measured by the two-stage test was below 10 per cent. Bleeding occurred in 15 of the patients. In 13 of the 15 patients the prothrombin level was below 11 per cent (two-stage method) when the bleeding became apparent and stopped when the prothrombin rose to between 15 and 20 per cent. In the other 2 cases, bleeding occurred following trauma, the prothrombin being 36 per cent at the time. The results of this study suggest that a range of 10 to 30 per cent (two-stage method) is a safe, efficient level for the maintenance of plasma prothrombin.

## MORPHOLOGY

EXPERIMENTAL INFARCTION OF BONE AND MARROW. *J. H. Bragdon, L. Foster and M. C. Sosman*. From the Department of Pathology, Harvard Medical School, Boston, Mass. Am. J. Path. 25: 709-723, 1949.

Literature concerning bone and marrow infarction contains many contradictory reports based on some instances on nonphysiologic experimentation. The present series of experiments, conducted on 25 skeletally immature rabbits (2.3-3.3 Kg.), extended over a period of one day to six months. Infarcts were produced by transecting the nutrient artery and in most cases the accompanying vein of the femur. At the termination of the experiments the femurs were cleaned and roentgenograms taken. Histologic preparations were made from fragments not over 2 cm. in length after decalcification in nitric acid. Tissue changes were detected in both bone and marrow twenty-four hours following infarction and were still evident after six months. In marrow infarcts the absence of a fibrous cicatrix was striking. Fat released from necrotic cells was engulfed by phagocytic cells. Hematopoiesis was diminished or absent. An unidentified yellow material, presumably lipid, was noted in macrophages. As a rule small areas of necrotic bone were located along the inner margins of the cortex of the shaft.

O P J

HISTOCHEMICAL STUDIES IN GAUCHER'S DISEASE. *R. W. Morrison and M. H. Hack*. From the Department of Pathology, University of Illinois College of Medicine, Chicago. Ill. Am. J. Path. 25: 597-603, 1949.

For quite some time the large foamy cells derived from the reticulum and histiocytes in the spleen

liver lymph nodes and bone marrow in Gaucher's disease have been known to contain kera<sup>1</sup>so a cerebroside. This substance is composed of lignoceric acid, sphingosine and usually galactose. Such a compound might be expected to produce a positive reaction with the periodic acid leukofuchsin method. This was confirmed by using pure kera<sup>1</sup>sin isolated from human brain. Microscopic localization of this histochemical reaction in sections from three spleens removed from patients with Gaucher's disease was made possible by the fact that the altered carbohydrate remains bound to the insoluble components of kera<sup>1</sup>so. Gaucher cells gave the brilliant rose purple color of a positive reaction. The periodic acid leukofuchsin method has differential diagnostic possibilities for lipid diseases because characteristic foam cells of Niemann-Pick's disease remain colorless.

## RADIATION AND RADIOACTIVITY

**THE RADIATION SYNDROME** *E. E. Painter and A. M. Bruce* From the Argonne National Laboratory, Chicago, Illinois. *New England J. Med.* 240: 871-876, 1949.

This article is a review of experimental data related to the toxic effect of radiation. The radiation syndrome is divided into the initial shock, the acute period, the subacute period and the chronic period. The authors point out how limited our knowledge is from the problem of how radiation produces cell damage to the interpretation of the many secondary metabolic effects which may be part of the general alarm reaction.

C A F

**THE METABOLISM OF THE RADIOACTIVE ELEMENTS CREATED BY NUCLEAR FISSION** *J. G. Hamilton* From the Crocker Laboratory and Division of Medical Physics (Berkeley), the Divisions of Medicine and Radiology (San Francisco), University of California. *New England J. Med.* 240: 863-870, 1949.

This article deals with the metabolism and tissue localization of products of nuclear fission. To evaluate the potential hazard of these radioactive isotopes, the substances were administered to rats orally by inhalation and by parenteral injection. There are 14 isotopes of importance and their half-life, fission yield, oral absorption, accumulation in the principal organ of retention and elimination are tabulated. Elements such as plutonium deserve special attention due to their skeletal localization and potential danger to the bone marrow. Radioautographs illustrate the osseous and pulmonary localization of some of these elements.

C A F

**THE EFFECT OF ROENTGEN RADIATION ON THE PRODUCTION OF THORACIC DUCT LYMPHOCYTES** *W. N. Valentine, C. G. Cradlock and J. S. Lawrence* From the Departments of Medicine and Radiation Biology, The University of Rochester School of Medicine and Dentistry, Rochester, New York. *Am. J. M. Sc.* 217: 379-382, 1949.

It has been widely recognized that lymphoid tissue is among the most sensitive indicators of damage by roentgen radiation. Further, after large doses of radiation the blood lymphocytes disappear very rapidly from the peripheral blood and are virtually absent in twenty-four hours. In this report changes in the numbers of thoracic duct lymphocytes and rate of flow of thoracic duct lymph in cats receiving a single dose of 1500 r whole body irradiation are recorded. Following this amount of irradiation the number of lymphocytes in thoracic duct lymph decreased rapidly.

# BONE MARROW NUTRITION IN RELATION TO THE PHAGOCYTTIC ACTIVITY OF BLOOD GRANULOCYTES

By CLARENCE A. MILLS, M D , PH D

PHAGOCYTOSIS has long been recognized as the body's first line of defense against invasion by micro-organisms, with the wandering blood granulocyte playing a particularly important role. Humoral factors which influence the phagocytic activity of these cells have received much attention as basically important elements in the immunity mechanism. Little work has been devoted, however, to the nutritional background of these cells at the time of their production in the bone marrow. Knowledge recently acquired indicates that it is just as important for these fighting units to be well born as it is for the whole individual, that granulocytes produced in the bone marrow during periods of malnutrition or vitamin deficiency remain poorly functioning units throughout their lifetime, while those arising from properly nourished marrow tissue emerge with, and maintain, full phagocytic activity.

In the large group of respiratory infections, and in numerous incidental exposures such as those of burns and wounds, our chief defense against bacterial invasion lies in the basic activity of the phagocytes, unreinforced by the humoral mechanism which may become an important stimulant to phagocytosis only after two to three weeks' exposure. It is therefore essential that we be aware of the conditions promoting or hindering the output of fully active phagocytic granulocytes from the bone marrow.

Development of a quick and relatively simple technic for measuring phagocytic activity of blood granulocytes<sup>1</sup> opened the way for an intensive study of the physiology of these cells in experimental animals kept on synthetic diets.

## METHODS AND RESULTS

A review of the literature concerning phagocytosis and consideration of the various possible techniques convinced us that our best chance to ascertain quantitative differences in phagocytic activity lay in the study of blood leukocytes *in vitro*. The following technic was used:

Under light ether anesthesia 0.5 ml. of blood is withdrawn from the rat's heart into a syringe previously rinsed in heparinized salt solution. This blood is immediately transferred to a paraffined tube of 10 mm. inside diameter and mixed with 0.5 ml. of salt solution containing  $\frac{1}{4}$  mg. of heparin. To this heparinized blood is added 0.1 ml. of a standard bacterial suspension (see below). Air is washed from the tube by a stream of  $O_2$ - $CO_2$  mixture (95%-5%) to maintain a normal blood gas level. The tube is stoppered with a paraffined cork and inverted twice for thorough mixing. It is then placed in a 38°C. water bath and agitated with a lateral motion (360 reversals of direction per minute) for four minutes. A sample is then removed with a small paraffined pipet and a smear is made which is dried and treated with Wright's stain. Four blood samples are usually run together as a group. Careful watch was kept at all times of the temperature of the water bath for changes greater than 1°C. produced distinct alterations in phagocytic activity.

Polymorphonuclear neutrophils of rat blood tend to clump much more readily than do those of man, especially after active ingestion of bacteria has taken place. With the technic just described, however, clumping is rarely observed. The second difficulty—still not completely solved—was a tendency of the
